ABSTRACT

The study was made on the role of ozone (O3) gas treatment on seeds of Lycopersicon esculentum cv. PKM1 (tomato) to release dormancy in advance. The experimental conditions followed a complete factorial design with 3 independent factors, i.e. A faster start of germination in T2 treatment (98% - 99%) was observed than in other treatments (T1, T3 and T4) compared to control seeds by measuring seedling growth rate on 5th day after treatment. Nevertheless a too long and high concentration of O3 treatment seemed to be penalizing on germination rate whereas low O3 concentration (T2) for a moderate time interval (20 min) seemed to be most beneficial. The treated seeds were stored, checked 1, 3, 6 months later and found that, the seeds have retained their accelerated germination efficiency. In particular, 1T2 (1 month storage), 3T2 (3 month storage) had maximum germination rate among all the stored treated seeds, but 6T2 (6 month storage) didn’t show sustained germination acceleration efficiency. Therefore, it was found that when time prolongs, O3 treatment loss its effect steadily and the germination efficiency of all the treatments are more or less same at six months after treatment. It is hypothesized that the application of O3 acts as an important phenomenon in accelerating seed germination by breaking the dormancy in advance which is associated with reduced level of ABA in O3 treated seeds.

Keywords: Abscissic Acid, Germination, Ozone, Tomato Seed

1. Introduction

Germination is the process which leads to elongation of the embryonic axis from a seed, allowing subsequent seedling emergence. Seed dormancy is defined as the failure of an intact viable seed to complete germination under favorable conditions and is controlled by several environmental factors, such as light, temperature and the duration of seed storage (after ripening) [1,2]. Dormancy may be related to the embryo itself or to its surrounding structures i.e., seed coat which lead to distinguish several classes of dormancy [3]. Dormancy and germination are determined by the co-action of the growth potential of the embryo and the restraints imposed by the tissues surrounding it. It is known that, when used in the natural state, seeds for agricultural production suffer from a certain number of deficiencies, giving rise in particular to a small germination percentage, to growth defects, and to pathology specific thereof.

Various studies have been done documenting the exogenous treatment of seeds to break seed dormancy. Scarification is the weakening of seed coats by mechanical abrasions or chemical treatments. Mechanically, the abrasions are caused by machine threshing, or chemical treatments. Chemically, the seeds are treated with chemicals like potassium nitrate, thiourea, ethylene, chlorohydrine to make the seed coats soft and weak. In addition the positive effects of oxidative stress on germination have also been documented [4,5].

The biological effects of ozone (O3) on plants have been studied for more than 50 years. Plants have evolved a complex of defence response mechanisms to respond various environmental stresses from morphological, biochemical and physiological changes triggered by O3 [6-8]. Ozone is a strong oxidant and it is an effective disinfectant because it has the unique ability to destroy toxic or noxious industrial impurities and inactivates biological (viral and bacterial) contaminants through the oxidation of double bonds [9]. In seeds, reactive oxygen species (ROS) production has been considered for a long time as being very harmful, since the works dealing with ROS were mainly focused on seed ageing or seed desiccation, two stressful situations which often lead to oxidative...
stress [10]. Numerous recent works have nevertheless brought new lines of evidence showing that the role of ROS in seeds is not as unfavourable as it was considered previously [11].

ROS derive from the reduction of oxygen which gives rise to superoxide (O$_2^-$), hydrogen peroxide (H$_2$O$_2$), hydroxyl radical (HO) and singlet oxygen (1O$_2$). ROS been playing a role in cellular signaling, and these compounds could facilitate the shift from a dormant to a nondormant status in seeds [10]. Indeed, it is known that ROS can accumulate during seed storage in the dry state, as previously mentioned [12-14]. There was a clear cut relationship between seed dormancy alleviation and accumulation of ROS and peroxidation products in cells of embryonic axes, thus suggesting that ROS might play a role of signal in dormancy alleviation [15,16]. Several reviews have described the signalling roles of ROS in plants and their role in plant growth and development is well documented.

Therefore, aim of the present study is to examine the influence of O$_3$ gas generation in eliciting ROS on tomato seeds to release dormancy in advance and the grounds for acceleration of germination will be deliberated.

2. Materials and Methods

2.1. Ozone Generation

Ozone gas was generated by passing dry oxygen gas through a corona discharge type O$_3$ generator (V can Network model M221), passed through a concentration equalization tank, and bubbled into the deionized water with a glass diffuser. The O$_3$ gas output was estimated with an O$_3$ analyzer kit (BMT 961).

2.2. Seed Material

*Lycopersicon esculentum* cv. PKM1 (tomato) seeds isolated from ripe fruits were used for the study. All the seeds used for the study were incubated in 1% HCl for 1 h to remove the remnants of the mucilaginous locular tissue. Subsequently, the seeds were rinsed with tap water, dried at room temperature, and stored in closed plastic container in a refrigerator at 7°C until use.

2.3. Seed Container Treatments

In order to investigate the effects of O$_3$ on germination, the seeds were sterilized in the laboratory using Sodium Hypochlorite of 7% for 1 hr and washed three times with sterile distilled water. Tomato seeds were humidified in a plastic flask and distilled water was added, until all the seeds were get completely immersed. For each treatment fifty seeds were used. Seeds were introduced in the reactor and treated with different O$_3$ concentration, T$_1$ = 0.001 grams per gram (g O$_3$ g$^{-1}$) of seeds, T$_2$ = 0.01 g O$_3$ g$^{-1}$ seeds, T$_3$ = 0.1 g O$_3$ g$^{-1}$ seeds and T$_4$ = 1 g O$_3$ g$^{-1}$ seeds were performed in the sterilized-diffusers for a various time duration of 10, 20 and 30 mins respectively. While for the control (C) tomato seeds, charcoal filtered air (CI-F) were passed. After treatment, seed were removed from the reactor, dried at room temperature, and stored in closed plastic container in a refrigerator at 7°C until use.

2.4. Germination Test

The germination tests were performed using treated seeds, by giving four different periods of rest time before germination test, i.e. 1) Germination test performed immediately after treatment (referred to as T$_1$, T$_2$, T$_3$ and T$_4$ seeds); 2) One month after treatment (referred to as 1T$_1$, 1T$_2$, 1T$_3$ and 1T$_4$ seeds); 3) Three months after treatment (referred to as 3T$_1$, 3T$_2$, 3T$_3$ and 3T$_4$ seeds), 4) Six months after treatment (referred to as 6T$_1$, 6T$_2$, 6T$_3$ and 6T$_4$ seeds). All the seeds including control seeds were sown in Petri dishes on one layer of filter paper (What- man No.1) moistened with 1.5 mL of 0.25 mg L$^{-1}$ thiomersal to prevent fungal growth, without growth regulator or osmotic material. The Petri dishes were sealed with Parafilm to ensure closed-system models. All the plates were placed in closed plastic boxes and incubated at 26°C ± 1°C in the dark unless otherwise mentioned. In experiments with intact seeds, visible radicle protrusion was used as the criterion for germination unless mentioned otherwise [17]. These experimental conditions followed a complete factorial design with 3 independent factors, *i.e.* O$_3$ concentration, treatment duration, and rest time before germination.

2.5. ABA Determinations

Quantitative determinations of endogenous ABA were performed according to techniques described by [18] using Gas chromatograph equipped with an electron capture detector. Recovery was determined with the use of ("4C) ABA that was added to the first extraction medium. It was shown to be at least 95%.

3. Results and Discussion

Seed dormancy and germination are very complex phenomena which involve tightly controlled signalling pathways and molecular regulations. Seed germination is sensitive to both endogenous plant growth regulators and environmental factors. Although ROS have been widely considered as detrimental to seeds, recent advances in plant physiology signalling pathways has lead to reconsider their role [19]. ROS accumulation can therefore be also beneficial for seed germination and seedling growth by regulating cellular growth, ensuring a protection against pathogens or controlling the cell redox status. ROS
probably also act as a positive signal in seed dormancy release. They interact with abscisic acid and gibberellins transduction pathway and are likely to control numerous transcription factors and properties of specific protein through their carbonylation [19].

Reports have shown that the transition from a quiescent seed to a metabolically active organism is associated with ROS generation, suggesting that it is a widespread phenomenon. Production of hydrogen peroxide has been demonstrated at the early imbibition period of tomato seeds [20]. Nitric oxide, hydroxyl radicals and superoxide radicals also accumulate during the germination of seeds of various species [21,22]. However, the external sources of ROS production and application methods are poorly documented. Therefore we made an attempt to demonstrate the influence of O₃ in generation of ROS in accelerating germination in tomato seeds.

When different concentrations of O₃ (T₁, T₂, T₃ and T₄) passed to tomato seeds and immediately tested for the germination efficiency of treatments, although germination was noticed in all treatments within 5 days, on the whole maximum frequency of germination of tomato seeds were observed in the 20 min O₃ treatment than 10 and 30 min treatment. Therefore, hereafter results are discussed only about the 20 min O₃ treatment, unless otherwise mentioned. Treated tomato seeds resulted in a faster germination rate vs. control samples. This early germination start led to a larger number of germinated seeds with longer roots at 5th day. A faster start of germination was observed in 0T₁, 0T₂ and 0T₃ ozone treated samples, whereas in 0T₄ doesn’t. The germination of tomato seeds after treatments (before storage) were 0T₁ = 86%, 0T₂ = 97% and 0T₃ = 78%, 0T₄ = 44% but for control (0C) 72 percentage germination was obtained (Table 1). Comparing to Control seeds, germination % is relatively higher in 0T₂ = 26%, followed by 0T₁ = 16% and 0T₃ = 8%. But, 0T₄ treatment shows 40% reduced germination than the control seeds. Nevertheless, too long an O₃ treatment seemed to be unfavorable for seed growth, whereas a short one seemed to be most beneficial. The O₃ treatment oxidizes the seeds and therefore, germination efficiency of the seeds decreased as the concentration (0T₄ = 40%) and treatment duration (30 min) of O₃ increased (Table 1). Tests performed on seeds of tomato, representative of major existing families, have shown that O₃ treatment without an additional agent serves to significantly improve the germination rate of the treated seeds.

Table 1. Effect of ozone treatments on germination of mature tomato seeds based on 3 independent factors, i.e. O₃ concentration, treatment duration, and rest time before germination.

Each value is the mean of three experiments with ten replications each (n = 3). Statistically the means of the three experiments were not significantly different (P < 0.05). Means in the same column of respective S.No. with different letters are significantly different at P < 0.05 in accordance with Fisher’s least significant difference test. T₁= 0.001 g O₃ g⁻¹ seeds, T₂ = 0.01 g O₃ g⁻¹ seeds, T₃ = 0.1 g O₃ g⁻¹ seeds and T₄ = 1 g O₃ g⁻¹ seeds were performed in the sterilized-diffusers for a time duration of 10, 20 and 30 min. While for the control (C) tomato seeds, charcoal filtered air (Cl-F) were passed. Seeds were given different rest time i.e. 1, 3, 6 months before germination. Treatments are referred to different categories i.e. 1 month (1C, 1T₁, 1T₂, 1T₃, 1T₄), 3 month (3C, 3T₁, 3T₂, 3T₃, 3T₄) and 6 month (6C, 6T₁, 6T₂, 6T₃, 6T₄) respectively.
In order to check, whether O₃ treated stored seeds retain the accelerated germination efficiency, it was checked and found that, all the T₂ seeds, i.e. 1T₂, 3T₂ and 6T₂ had maximum germination rate compared to other stored seeds (T₁, T₃, T₄ seeds). Among the T₂ stored seeds, 1T₂ shows 24% and 3T₂ shows 22% enhanced germination compared to control but 6T₂ didn’t show sustained germination acceleration efficiency i.e. O₃ treated seeds have more or less same or vaguely (negligibly) higher in germination frequency (9%) compared to control seeds. We infer that the seeds lose its temperament when time prolongs and posses more or less normal germination efficiency as that of control. The seeds of T₃ and T₄, O₃ treated for 30 min duration were found to be injured and when time prolongs the seeds recovered from the injury (1T₃ = 21%, 3T₃ = 10%; 1T₄ = 50%, 3T₄ = 43%, and 6T₄ = 37%) and show enhanced germination (6T₁ = 21%) compared to initial stage. Therefore it was found that when time prolongs, O₃ treatment loss its effect steadily and the germination efficiency of all the treatments are neither more or less same nor meagrely higher at six months after treatment. The data from our present study show that inducing dormancy could be break up by O₃ treatment to the seeds resulted in an oxidative stress, which allows the seeds to germinate. It now appears more and more clear that ROS would play a key signalling role in the achievement of major events of seed life, such as germination or dormancy release.

In developing or germinating seeds, the active mitochondria are probably one of the major sources of ROS, generating superoxide, and subsequently H₂O₂ [23]. In seeds of some species, such as tobacco, tomato, pepper or Arabidopsis, germination is constraint by the micropylar endosperm, which covers the radicle tip [24]. Germination can proceed if the mechanical resistance imposed by the endosperm decreases to such a level that radicle can protrude through the weakened tissues. The GA₃/ABA ratio is the most important hormone factor, which promote germination in seeds and led to improved germination performance [25]. This endosperm weakening is under the regulation of abscisic acid (ABA) and gibberellic acid (GA) and several hydrolases have been suspected to contribute to cell-wall loosening [26]. There is an increasing bundle of evidence suggesting that ROS would play a key role in this phenomenon and it has been proposed that they would be involved in cell wall loosening in growing tissues. Therefore, in order to examine the cause of O₃ treatments on seed germination, ABA contents were analyzed (Table 2). Among the treatments, T₂ treatment significantly reduced (5 fold) the ABA level in seeds compared to other treatments T₁ (1 fold), T₃ (2 fold) and T₄ (below 1 fold). The results revealed that the ABA levels were drastically reduced compared to mature control seeds (Table 2).

There are also antagonistic effects of ABA and ethylene on dormancy and germination. Stimulation of ethylene synthesis by environmental stresses, such as O₃, UV irradiation, and wounding, involve generation of reactive oxygen species [27]. Some responses of plant tissue to O₃ fumigation may be due to active production of ethylene by the injured tissue [28]. Tomato, tobacco, and bean plants treated with O₃ had increased rates of ethylene production [29]. Ethylene may promote germination by interfering with the ABA action on seed dormancy and/or maintenance of dormancy [30]. In some species, such as sunflower, ethylene can break seed dormancy [31]. Several components of the ethylene signal transduction have been identified and their signaling pathway has been characterized [32]. Ethylene signal transduction mutant studies highlight the interaction between ABA and ethylene signaling suggesting that ethylene suppresses dormancy by inhibiting ABA action [32]. The results from our study also confirm that the O₃ treatment suppresses the ABA level significantly which may be due to the association of ethylene.

The elicitation of GA₃ at mild concentration of O₃ was observed [33], whereas, no statistically significant differences were found in the GA₃ levels between the controls and the needles of trees which were treated with increased levels of O₃. Similarly, from the results of our study it is anticipated that the generation of mild concentration of O₃ (T₁ and T₂) on the seeds could elicit higher level of GA₃ rather than the other treatments (T₃ and T₄) (Table 1).

On the one hand, there exists evidence suggesting that hydrogen peroxide alleviates seed dormancy. It was already reported that H₂O₂ reverse the inhibitory effect of ABA upon endosperm rupture, underlining the cross talk between these two compounds [34]. Antioxidants which

The seeds were extracted at harvest (nondried) and each value in the data represent the mean of three experiments with ten replications each (n = 3). act as ROS scavenger in seed biology play a very important role in the growth processes occurring at early embryogenesis during seed development, participate in the mechanisms underlying radicle protrusion during seed germination and seed aging [35,36]. Exogenous H₂O₂ stimulates the germination of dormant seeds of barley, Fontaine et al. 1994; rice, [37] apple [38] and tomato [20]. Treatment of dormant barley seeds with hydrogen peroxide results in a decrease in endogenous ABA level [39] and alleviation of apple embryo dormancy by cyanide induces a simultaneous increase in H₂O₂ level and decrease in ABA content [38]. H₂O₂ promoted seed germination in a dose-dependent manner as did respiratory inhibitors, indicating that H₂O₂ itself possibly promotes seed germination rather than O₂ [40]. Therefore, in the present study, it is predicted that H₂O₂ activity in tomato endosperm would have greatly enhanced when the tissue was rupture, or wounded by the generation of O₃ which results in the radicle penetration through the micropylar endosperm.

In general, the reaction of O₃ on the surface of seeds takes place by way of a gas-solid type interchange, followed by diffusion within the structure. Among the possible interplay between ROS and plant hormones, the relationship between H₂O₂ and ABA appears as the most probable. Oxidative stress accelerates the accumulation of H₂O₂ in seeds. The hypothesis shown postulates that ROS play a central role with hormones and particularly ABA, in dormancy release and germination completion. After treatment there is an accumulation of ROS by non-enzymatic ROS production. This accumulation might reduce ABA level and/or block ABA signalling, stimulate GA and ethylene signalling, modify redox status and downstream events and alter protein function through oxidative modifications.

The present work constitutes the basis for the future invention that it is possible to improve the germination properties and/or the growth of seedlings by treatment with O₃, preferably produced from vector gases, without calling on an additional oxidizing agent, and with the treatment being relatively short in duration, ease in handling at very low cost. In general it is authenticated that, the person skilled in the art will find it relatively easy to determine the optimum conditions for implementation of the process.
