ABSTRACT
The Lambert W function has its origin traced back 250 years, but it’s just been in the past several decades when some of the real usefulness of the function has been brought to the attention of the scientific community.

Keywords: Lagrange Inversion Theorem; Infinite Tower of Exponents

1. Introduction
The Lambert W function, named after Johann Heinrich Lambert [1], is a standard function in both Mathematica, where it’s called Product Log(x), and in Maple, where you can use both Lambert W(x) or Lambert W(0,x). The zero in this latter expression denotes the principal branch of the inverse of $e^x$. The actual usage of the letter W has a rather vague origin. One source attributes it to some earlier papers on the subject that wrote the standard equation as $we^w = x$ using a small $w$. Programming protocol with Maple then forced the letter to be capitalized [2]. Another source [3] attributes the W to honor the British mathematician Sir Edward M. Wright (famous co-author with G. H. Hardy of An Introduction to the Theory of Numbers) who did a lot of pioneering work with the function. Finally, Robert Corless and David Jeffrey of the University of Western Ontario have written, during the past several decades, a number of journal articles on the function. Their paper in 1996, in collaboration with Gaston Gonnet, David Hare, and Donald Knuth, was where Lambert’s name got attached to the function [2]. It could have been coined the Euler W function, since Euler had studied the equation $xe^x = \alpha$ [4] (although Euler credits Lambert as studying the equation first [5]), but they decided Euler had enough items attached to his name!

2. Definition
The exponential function $y = xe^x$ is defined for all real $x$, but has a codomain of $y \geq \frac{-1}{e}$. This function (Figure 1(a)) is the product of two elementary functions, each defined on the entire real line, and each being one-to-one; but the product is not injective. Consequently, if we restrict the domain to $x \geq -1$, then $xe^x$ will possess an inverse, which is a function, and it’s this function that is now known as the (principal) Lambert W function (Figure 1(b)), written as $W(x)$. An alternative branch for $W$ would be defined for that portion of $xe^x$ when $x \leq -1$. We won’t consider that situation in this article.

Several function values of W are easy to compute, such as $W(-1/e) = -1$, $W(0) = 0$, $W\left(-\frac{1}{2}\ln 2\right) = -\ln 2$, and $W(e) = 1$. The value of $W(1)$, known as the omega constant, has the approximate value 0.567143. The number $W(1)$ is, in some sense, a distant cousin of the golden ratio $\phi$, since $1/\phi$ is a solution to $1/x = x + 1$, and $W(1)$ is the solution to $1/x = e^x$, and $x + 1$ is the linear Maclaurin approximation to $e^x$ (Figure 2). Since $W$ is the inverse of $xe^x$, it follows that $W(1)e^{W(1)} = 1$ and that the slope of the curve in Figure 1(b) at the point $(1, W(1))$ is $\left[1 + e^{W(1)}\right]^{-1} \approx 0.6381$.

3. Computation
A natural question is how to compute arbitrary values of $W(x)$. One result, from the Lagrange inversion theorem, asserts that the Lambert W function has the Taylor series expansion [6,7]

$$W(x) = \sum_{n=1}^{\infty} \frac{(-n)^{n-1}}{n!} x^n, \quad (1)$$

which, unfortunately, has a radius of convergence of merely $1/e$. Since the denominator $n!$ grows rapidly it’s...
advantageous to write the series with the coefficients defined recursively as \( W(x) = \sum_{n=1}^{\infty} c_n x^n \), with 

\[
c_1 = 1, \quad c_n = -\left( \frac{n}{n-1} \right)^{n-2} c_{n-1}, \quad \forall n \geq 2.\]

This recursion lends itself to easy programming evaluation. Testing this, with say a series of 150 terms (which is plenty, considering that \( |x| \leq \frac{1}{e} \)), with \( x = -\frac{1}{\ln 2} \approx -0.3465736 \), we obtain a partial sum value of \( -0.69314684 \), which differs from the exact value of \( -\ln 2 \) by 0.0000003. We also note that \( |x| < \frac{1}{e} \), so the use of the series is justified.

On the other hand, a TI-graphing calculator returns “overflow error” if we try to determine \( W(1) \), primarily since the coefficients grow rapidly.

Suppose that \( |x| > \frac{1}{e} \) and we wish to compute \( W(x) \). One possibility is the series

\[
W(x) = \ln x - \ln(\ln x) + \sum_{n=1}^{\infty} \frac{(-1)^n}{n} a_n(x) \quad (2)
\]

where \( a_n(x) = \sum_{m=1}^{n} (-1)^m S(n, n-m+1) \left[ \ln(\ln x) \right]^m / m! \) and \( S(n, k) \) denotes a Stirling number of the first kind [3]. The series (2) is somewhat impractical to use because of the difficulty in determining \( a_n(x) \); it turns out to be more useful to employ some standard numerical schemes for approximating \( W(x) \).

First, setting \( W(x) = y \), we need to solve \( ye^y = x \). Defining the function \( g \) by \( g(y) = ye^y - x \), we use Newton’s method to approximate \( y \) in \( g(y) = 0 \). This gives \( y_{n+1} = y_n - \frac{g(y_n)}{g'(y_n)} = y_n + xe^{y_n} / y_n + 1 \). To determine \( W(2) \), for example, starting with an initial approximate of \( y_0 = 0 \), after 7 more iterations we get \( y_8 = 8.52605502 \), which is an excellent approximation to \( W(2) \) because \( ye^y \) returns 2 on the calculator. If \( x \) is a relatively small number, then an initial approximate of 0 will suffice for the algorithm; but if \( x \) is large, then \( \ln x \) can be chosen for \( y_0 \). For instance, if \( x = 10 \), choose \( y_0 = \ln(10) \), and after 5 iterations we get \( W(10) \approx 1.745528003 \).

Newton’s method is a favorite iteration scheme for many because of its simplicity, though the convergence, quadratic in general, is typically relatively slow. A faster choice is furnished by Halley’s method (of Halley’s comet fame), which produces cubic convergence, and happens to be the choice implemented by the software Maple; this scheme gives [8]
\[ y_{n+1} = y_n - \frac{y_n e^{y_n} - x}{(y_n + 1)e^{y_n} - (y_n + 2)(y_ne^{y_n} - x)} \cdot (y_n + 1) e^{y_n} - \frac{y_n e^{y_n} - x}{2y_n + 2}. \]

Employing this gives \( W(10) = 1.745528003 \) after 3 iterations. This complex looking scheme is actually what you get when you apply Newton’s method to the function \( g(x) = y \frac{e^{y_n} - x}{(y_n + 1)e^{y_n} - x} \). An alternative root-finding scheme, using continued fraction expansion, is described in [10].

4. Calculus

We know that since \( y = xe^x \) is an increasing and differentiable function for all \( x > -1 \) then its inverse \( y = W(x) \) is likewise increasing and differentiable for all \( x > -\frac{1}{e} \).

Differentiating this latter equation with respect to \( y \), we obtain

\[ 1 = \frac{dW}{dx} \frac{dx}{dy} = \frac{dW}{dy} \left(y e^y + e^y\right), \]

so

\[ W'(x) = \frac{y}{(y+1)e^y} = \frac{W(x)}{(y+1)x} = \frac{e^{-W(x)}}{1 + W(x)}, \quad x \neq 0. \]

In particular, \( W'(e) = \frac{1}{e[1+1]} = \frac{1}{2e} \), and similarly,

\[ \lim_{x \to 0}(W'(x)) = \infty. \]

What about the right-hand side of (3) is indeterminant at \( x = 0 \), but division of both sides of (1) by \( x \) and taking the limit as \( x \to 0 \) gives

\[ \lim_{x \to 0} \frac{W(x)}{x} = 1. \]

For large \( x \), the graph of \( W(x) \) bears strong resemblance to \( \ln x \), since from (2) we have \( \lim_{x \to \infty} \frac{W(x)}{\ln x} = 1 \), although we have to be careful here because the difference \( W(x) - \ln x \) increases without bound as \( x \to \infty \) [7]. The graph of \( W(x) \), like that of \( \ln x \), is concave downward for all \( x \) since \( xe^x \) is concave upward. If we differentiate (3), and omit the argument \( x \) for brevity, then

\[ W'' = \frac{x(1+W)W' - W[xW' + 1 + W]}{x^2 (1+W)^2} = -\frac{2W^2 - W^3}{x^2 (1+W)^2} < 0. \]

Rewriting \( W* \) as \( \frac{e^{-W}[-(W+2)]}{(1+W)^2} \) puts this into the form which fits the general case for \( W(x) \) [5]. In fact, from this form, we readily see that there is a point of inflection on the curve when \( W = -2 \), which actually falls on the other branch of the \( W \) function.

Continuing along the calculus vein, we should examine, if possible, the integral of \( W(x) \). To this end, recall that \( y = W(x) \) iff \( ye^y = x \). Thus,

\[ \int W(x) \, dx = \int y \frac{dy}{W'(x)} = \int \frac{ydy}{W(x)} x(1+W(x)) \]

and integrating this last integral by parts, we obtain

\[ \int W(x) \, dx = x \left[W(x) - 1 + \frac{1}{W(x)}\right] + C. \]

In particular, the area of the region bounded by the curve \( W(x) \), the \( x \)-axis, and the line \( x = e \) is, therefore,

\[ \int_0^e W(x) \, dx = e \left[W(e) - 1 + \frac{1}{W(e)}\right]_0^1 = e - 1. \]

We note this result agrees with evaluating the integral via inverse functions [11], because then

\[ \int_0^e W(x) \, dx = e W(e) - 0 W(0) - \int_0^{W(e)} xe^x \, dx = e - 1. \]

Other integrals, involving functions containing \( W \), can be computed, some just with a special change of variable [6]. For instance,

\[ \int W(x) \, dx = \int \frac{1}{2} \left[e^{2W(x)} \left[W(x) - \frac{1}{2}\right] \left[W^2(x) + \frac{1}{2}\right] + C. \]

The function \( xW(x) \) is concave up, connecting \((0,0) \) and \((e,e) \), hence its area \( \int_0^e xW(x) \, dx = \left(3e^2 + 1\right)/8 \) is less than \( \int_0^e xdxe^x = e^2/2 \). Similarly we find

\[ \int_0^e \frac{x}{W(x)} \, dx = -4 \left[3e^2 + 1\right]/4, \]

and this is greater than \( e^2/2 \) since \( xW(x) \) is increasing and concave down from \((0,1) \) to \((e,e) \).
5. Applications

An article appeared in the February, 2000, issue of FOCUS, the newsletter of the Mathematical Association of America, touting the merits of the W function as a candidate for a new elementary function to be studied in schools and to be included in textbooks [12]. The rationale for this was that not only is W a radically different function from the traditional elementary functions of polynomials, rationals, exponentials, logarithmics, and trigonometrics, but its calculus provides a wealth of interesting, and powerful, applications. A number of these are mentioned in a paper by Corless et al., where they describe such applications as enumeration of trees, combustion, enzyme kinetics, linear delay equations, population growth, spread of disease, and the analysis of algorithms [3]. An article [13] by Packel and Yuen shows that W is instrumental in determining the maximum range for a projectile with linear resistance (problems of this type have certainly been important for several thousand years). The solution for the current in a series diode/resistor circuit can also be written in terms of W. Applications of W are found in complex cases involving atomic, nuclear, and optical physics. The first physics problem to be solved explicitly in terms of W was one in atomic, nuclear, and optical physics. The first physics problem to be solved explicitly in terms of W was one in

Since the right-hand side of this last equation is of the form \( z e^z \), and since we know \( y = ze^z \) iff \( z = W(y) \), then \(-x \ln 2 = W(-\ln 2/10)\), or \( x = -\frac{1}{\ln 2} W\left(\frac{-\ln 2}{10}\right)\).

Using Kalman’s log function we can solve \( 2^x = 10x \) and get \( x = -\frac{1}{\log 2} g \log \left(\frac{10}{\log 2}\right) \). Since

\[ -\frac{\ln 2}{10} \approx 0.069 < \frac{1}{e} \]

we can use (1) to approximate

\[ W\left(-\frac{\ln 2}{10}\right) \]

and get \(-0.0746900848\), so

\[ x = 0.1077550149 \].

Checking, we find \( 2^x = 1.07755015 = 10x \).

The equation \( 2^x = 10x \) is a special case of a more general setting \( a^{bx+c} = dx + e \), where we assume the base \( a > 0 \) and where neither \( b \) nor \( d \) equals zero. The substitution \(-t = bx + \frac{be}{d}\) then gives

\[ a^{bx+c} = e^{(t-\frac{be}{d})} a^d = e^{-\frac{td}{b}} - \frac{be}{b} + e = -\frac{td}{b} \]

and, thus,

\[ a^{\frac{be}{d}} = a^{\frac{e}{a}} \]

Multiplication of both sides by \( \ln a \) gives

\[ \frac{-b}{d} (\ln a) a^{\frac{e}{d}} = t (\ln a) e^{\frac{e}{a}} \]

which now has the form

\[ u = we^u \]

so \( w = W(u) \), or \( t \ln a + W\left(-\frac{b}{d} \ln a \cdot a^{\frac{e}{d}} \right) \) and, hence,

\[ -bx + \frac{be}{d} = t = \frac{1}{\ln a} W\left(-\frac{b}{d} \ln a \cdot a^{\frac{e}{d}} \right) \]

that is,

\[ x = -\frac{1}{b \ln a} W\left(-\frac{b}{d} \ln a \cdot a^{\frac{e}{d}} \right) - \frac{e}{d} \]

Another interesting algebraic application involves the infinite tower of exponents \( x^{x^x} \), which will be denoted by \( T(x) \). To solve the particular equation \( T(x) = 2 \) one might argue that this is equivalent to \( x^{x^{x^{x^{...}}} = 2} \), in which case we have \( x^2 = 2 \), so \( x = \sqrt{2} \), which is the correct solution to \( T(x) = 2 \). But what about \( T(x) = 3 \), \( T(x) = 4 \), or \( T(x) = y \)? It stands to reason that as \( y \) increases, so does \( x \). But with \( T(x) = 4 \), we can write this as \( x^{x^{x^4}} = 4 \), or \( x^4 = 4 \), so \( x = \sqrt[4]{2} \) again! Something isn’t right.

The problem lies with the domain of \( T \). We find in [19] that the infinite tower of exponents is only defined (i.e.,
its interval of convergence) for \( \frac{1}{e^x} \leq x \leq \sqrt{e} \), or approximately \( 0.065988 < x < 1.444667 \). So if \( x \) is selected from this interval, what is \( T(x) \)? If we set \( T(x) = y \) then

\[
x^{T(y)} = y \Leftrightarrow \ln x \cdot e^{y \ln x} = y \ln x \Leftrightarrow W(-\ln x) = -y \ln x \Rightarrow \frac{W(-\ln x)}{-\ln x} = y.
\]

Note also that \( y = 1 \) when \( x = 1 \), and the above expression for \( y \) gives a function continuous at \( x = 1 \), since \( \lim_{u \to 0} \frac{W(u)}{u} = 1 \). Hence, if \( \frac{1}{e^x} \leq x \leq \sqrt{e} \), then \( e \geq -\ln x \geq -\frac{1}{e} \), so \( \frac{1}{e} \leq y \leq e \), and this is why the equation \( T(x) = 2 \) is solvable, but \( T(x) = 4 \) is not.

The graph of \( T \) is an increasing function with domain \( \left[ \frac{1}{e^x}, \sqrt{e} \right] \) and range \( \left[ \frac{1}{e^x}, e \right] \). It also passes through the two obvious points of \( (1,1) \approx \left( \frac{1}{e^x}, 0.567143 \right) \) and \( (1,1) \). What else can we deduce? Checking for differentiability, we have from (3),

\[
T'(x) = \frac{-W(-\ln x)}{-\ln x} \left[ 1 + \frac{1}{x} \right] - W(-\ln x) \left[ \frac{1}{x} \right] = \frac{W(-\ln x)}{x \ln^2 x} - W(-\ln x) \frac{1}{x \left[ 1 - (\ln x)T(x) \right]},
\]

and since the limit of this expression is 1 as \( x \to 1 \), then \( T'(1) = 1 \), and hence \( T' \) is never 0, so \( T \) is always strictly increasing. The following small table (Table 1) of values will prove helpful.

Alternatively, we could have found \( T' \) by implicit differentiation of \( y = x^y = T(x) = x^y \). Thus

<table>
<thead>

</tr>
</tbody>
</table>

Figure 3. Graph of \( y = e^{-x} \).

\[
\frac{1}{x} \cdot y' = y' = \frac{y'}{x-y \ln x} \quad \text{or} \quad y' = \frac{y^2}{x - xy \ln x} \quad \text{so again} \quad y'(1) = 1.
\]

Use of this form for easier access to \( y'' \) then gives, after some algebraic manipulations and cancellations,

\[
y'' = \frac{y^3 (2 - y \ln x) + y^2 (y - 1 + y \ln x)(1 - y \ln x)}{x^2 (1 - y \ln x)^3}.
\]

This complex expression appears to yield negative values for all \( x < 0.394 \) and positive values for all \( x > 0.394 \), and \( y''(0.394) \approx 0 \). Hence, we have an inflection point at \( x \approx 0.394 \), and \( y'' \approx 0.5817 \). Also \( y''(0.394) = \frac{0.5817^2}{0.394 \times \left[ 1 + 0.9314 \times 0.5817 \right]} \approx 0.557 \). Putting all of these pieces of the puzzle together, we obtain a decent graph of \( T \), as shown in Figure 3.

The tower function \( T \) must necessarily possess an inverse \( T^{-1} \). We note then that

\[
T(x) = y \Rightarrow x^{T(y)} = y \Rightarrow x^y = y \Rightarrow x = y^{1/y}
\]

and, consequently, this inverse is \( T^{-1}(x) = x^{1/y} \). Composition of the two functions gives the interesting pair of identities,

\[
\left( x^{1/y} \right)^{1/y} = x, \quad \frac{1}{e^x} \leq x \leq e \quad \text{and} \quad \left( x^{1/y} \right)^{1/y} = x, \quad \frac{1}{e^x} \leq x \leq \sqrt{e}.
\]
