ABSTRACT

Yerba mate (*Ilex paraguariensis*) is an indigenous crop which is highly consumed as an infusion in the South American subtropical forest. It has a high concentration of antioxidant substances, providing health benefits and helping to prevent diseases. The objectives of this work were to characterize an aqueous yerba mate extract by spectrophotometric and chromatographic (HPLC) methods and to study the effect of the freeze-drying process on the polyphenols profile and antioxidant activity, determined by a novel method. An aqueous extract was obtained and lyophilized to obtain a yerba mate powder with antioxidant properties. The extracts showed a high polyphenol content, determined by Folin-Ciocalteau and HPLC, and a high antioxidant activity towards the DPPH\(^{•}\) radical and after the recently developed method of photochemiluminescence. A linear correlation was found between Folin-Ciocalteau and DPPH methods for lyophilized samples. HPLC analysis allowed determining antioxidant components like rutin, caffeine and chlorogenic acid. Lyophilization caused a decrease in total polyphenol content and antiradical activity of the extracts and this fact was mainly attributed to changes in the chlorogenic acid related compounds and rutin structures, after their photochemiluminescence data. The photoluminiscent method proves to be an advantageous approach for antioxidant capacity determination.

1. Introduction

Yerba mate (*Ilex paraguariensis Saint Hilare*) is an indigenous bush from the subtropical forest of South America. Since the XV century, yerba mate has been consumed in Argentina, Paraguay, Uruguay and Brazil. Natives from this region, *guaraníes*, macerated the leaves to drink the infusion as a medicine for several diseases (rheumatics, intestinal and other disorders). Nowadays, this energetic beverage is also a source of vitamins and minerals and is included in several codices and worldwide pharmacopeias, like Argentine Food Code, Latinamerican Food Code, British Herbal Pharmacopoeia, etc. One of the distinctive characteristics of yerba mate is its high concentration of antioxidants, mainly caffeoyl derivatives and flavonoids, which are very important for health care. These substances counteract the action of free radicals, which are responsible for early aging processes and degenerative diseases. The main role of antioxidants is to delay or prevent the oxidation of the substrate, either in food or, after assimilation, in the human organism. The incorporation of natural antioxidants into food products is the common trend to both extend shelf life and supply extra health benefits. However, these additives often show little stability and their production and incorporation costs should be considered. For this purpose, quick and reliable measurement methods for its antioxidant power are required. Several authors found evidence that yerba mate extracts prevent DNA oxidation and *in vitro* LDL lipo-
peroxidation ([1,2]). Gugliucci and Stahl [3] attributed to yerba mate an antiatherogenic effect after showing the protection of LDL particles towards oxidation in vitro and in vivo. LunCEFORD and GUGLIUCCI [4] proved that aqueous yerba mate extracts inhibit the formation of glycation end-products which lead to complications in diabetic patients. ANESINIS, FERRARO and FILIP [5] proved the peroxidase-like activity of yerba extracts and also their chemoprotective and antioxidant capacity.

Lyophilization is a widely used process in the food industry although it could modify the antioxidant composition of some natural extracts, leading to nutritional losses. On this regard, RODRIGUEZ DE SOTILLO, HADLEY and HOLM [6] found that caffeic acid was degraded and gallic acid content was increased after freeze-drying antioxidant extracts of potato waste, without changes in Total Phenolic Content (TPC). Several authors have reported the polyphenol composition and the antioxidant activity of yerba mate extracts, measured by different methods ([7,8]). However, comparisons between liquid and lyophilized extract compositions obtained by different techniques have not yet been established for this plant material.

The objective of this work was to characterize liquid and lyophilized yerba mate extracts by spectrophotometric and chromatographic (HPLC) methods to find a relationship between the analytical techniques used. The relatively novel photoluminiscent method was also evaluated and compared. The effects of the lyophilization process on the polyphenols profile and the antioxidant activity of the extract were also analyzed.

2. Materials and Methods

2.1. Preparation of Extracts

Extracts were obtained from commercial yerba mate (Ilex paraguariensis) samples (“La Merced, de campo”, Las Marías, Corrientes, Argentina); 2 g of yerba mate with 100 ml of distilled water were placed in a thermostatic bath (Haake, Germany) at 100°C for 40 min. Once obtained, the extracts were filtered, kept in dark flasks and immediately cooled in an ice bath until analyzed. Liquid samples were frozen at −20°C during 24 h, transferred to a −80°C freezer for 24 h, and finally, freeze-dried (Heto FD4, Denmark) for 48 h at −50°C under vacuum. The powders were stored in hermetic flasks in a desiccator. The yield of the whole process was calculated as the weight of lyophilized sample (g) obtained from the extracted liquor, per gram of initial dried yerba mate. The UV spectra of liquid extract thoroughly diluted and lyophilized, dissolved in distilled water to reach an equivalent concentration, were determined from 200 to 800 nm in a spectrophotometer (Shimadzu, UV-mini 1240, Japan). The solubility of lyophilized yerba mate extracts was determined dissolving 100 mg of freeze-dried extract in 1 ml of distilled water. The suspensions were stirred, left to rest for 24 h and centrifuged at 1090 g for 10 min at 25°C (Beckman Coulter, Avanti J-25, USA).

2.2. Chromatographic Analysis

Chromatographic analysis was performed in an HP 1100 liquid chromatograph (Hewlett Packard, US) equipped with a binary pump, thermostated column compartment, auto injector, degasser and diode array detector (DAD) connected to an HP workstation. A Zorbax 300 SB-C18 column (250 × 4.6 mm, i.d.), packed with 5 μm particles and connected to a guard column, was utilized. The mobile phases “A” and “B” consisted of a mixture of water, methanol and formic acid (79/7/20/0.3) and a mixture of methanol and formic acid (99.7/0.3), respectively. A staggered gradient elution program at 0.9 ml/min prepared as follows: 0% B/15 min, 10% B/15 min; 30% B/10 min; 60% B/10 min; 80% B/2 min, was employed. Finally, the mobile phase composition returned to 0% B in 5 min, and this composition was maintained for 10 min to equilibrate the original solvent composition of the stationary phase. Rutin, quercetin, kaempferol, caffeine, chlorogenic acid, gallic acid and caffeic acid were used as standards for identification. Their retention times, DAD spectra stored in the library and the extract samples spiked with each standard were used for identification purposes. Stock solutions of each standard (0.25 mg/ml) were prepared in 50% methanol-water, bubbled with nitrogen and stored in the refrigerator until use. Calibration curves at four different concentration levels were performed. Each level was tested by triplicate. Based on the absorption maxima, the wavelengths selected for the calibration curves were 280 nm for caffeine, 330 nm for chlorogenic and caffeic acids and 360 for rutin. Fresh samples of liquid extract were transferred to a syringe-driven filter (Millipex-GS, 0.22 μm) and then were analyzed; for comparison purposes, equivalent amounts of lyophilized extract were solubilized in water. Results were expressed as mg of polyphenol compound/g of dried yerba mate.

2.3. Total Polyphenol Determination

Total polyphenol content was determined by the Folin-Ciocalteau method (TPCFC). This test is based on the oxidation of phenolic groups with phosphomolybdic and phosphotungstic acids. A green-blue complex with absorption between 725 and 750 nm is obtained after a given reaction time. Two milliliters of Na2CO3 (2% w/v) (Anedra, Argentina) were mixed with 200 μl of the yerba extract were transferred to a syringe-driven filter (Millex-GS, 0.22 μm) and then were analyzed; for comparison purposes, equivalent amounts of lyophilized extract were solubilized in water. Results were expressed as mg of polyphenol compound/g of dried yerba mate.

Copyright © 2013 SciRes. FNS
mate liquid extract, left 2 for min in darkness and finally 200 µl of Folin-Ciocalteau reagent (Anedra, Argentina, 1:1) were added. The absorbance of these samples was measured at 725 nm in a spectrophotometer (Beckman DU 650, USA) after 30 min time reaction. TPC_{FC} was also determined on the reconstituted samples of lyophilized yerba mate extracts, to analyze the effect of the drying process. Gallic acid (Sigma-Aldrich, US) and chlorogenic acid (Fluka, US) were used as standards. Results were expressed as mg standard equivalent/g yerba d.b. (dried basis).

2.4. Antioxidant or Antiradical Activity

The photochemiluminescence (PCL) inhibition capacity of samples and pure compounds (chlorogenic and caffeic acids, rutin and caffeine) was determined as described by Popov and Lewin [9]. An automated PCL inhibition capacity analyzer system (Photochem, Analytik Jena AG, Jena, Germany) was used. Liquid extract, lyophilized extract and pure compounds, either diluted or dissolved in mili-Q water, were analyzed using the kit for integral Antioxidative Capacity of Water-soluble substances (ACW). Fresh samples of liquid extract were transferred to a syringe-driven filter (Millex-GS, 0.22 µm) and then were analyzed; for comparison purposes equivalent amounts of lyophilized extract were solubilized in water. Results were expressed as mg of ascorbic acid equivalents per g of dried yerba mate, in the case of extracts, or per g of compound, in the case of standards.

Antiradical activity was determined by using DPPH• (Sigma-Aldrich, US) as a free radical. The method was adapted from Brand-Williams, Cuvelier and Berset [10] and is based on the reaction of specific compounds or vegetal extracts with the radical in an ethanolic solution. DPPH• reduction is followed by measuring the decrease of absorbance at 517 nm while the reaction occurs. Different concentrations of yerba mate extract were tested: 0.47 - 15.0 and 0.65 - 21.0 mg yerba mate/ml for liquid and lyophilized samples, respectively. A volume of 100 µl of each sample was added to 3.9 ml of DPPH• ethanol solution (25 mg DPPH•/ml ethanol). The decrease in absorbance was determined every 0.5 min for 10 min, and then every 15 min until the reaction reached a plateau. Gallic and chlorogenic acids were used as standard compounds for antiradical activity determination, as well.

EC_{50}, the amount of yerba mate extract needed to decrease the initial DPPH• concentration to 50%, and T_{EC50}, the time necessary to reduce the radical to this concentration, were determined according to Sánchez-Moreno, Larraúri and Saura-Calixto [11].

2.5. Relationship between TPC_{FC} and Antioxidant Activity

Analysis of antioxidant activity with DPPH• radical involves a higher economic cost and assay time. Thus, to find an easy way to characterize the antiradical activity of extracts during production, a possible linear relationship between Folin-Ciocalteau and DPPH• methods was studied. Linear models were fit to experimental data using a statistic program SYSTAT INC (Evanston, US).

3. Results and Discussion

3.1. Preparation of Extracts

Water was selected as the solvent for obtaining the yerba mate extracts, mainly to facilitate their use as food additive, although other solvents may be more efficient [12]. Besides being a green solvent, no further evaporation step is necessary. Process yield, including the lyophilization step, was 32.7% on dry basis of yerba mate. Yield values between 25% and 33% were also reported [8]. Depending on the industrial processing step (green leaves, zapécdaco, drying, and forced aging) of the vegetal mate, values between 25% and 33% were obtained [13]. Powder yerba mate extracts showed a water solubility of 96% and a moisture content of 3.8%. Similarly, Sinija, Mishra and Bal [14] reported a moisture content of 3% - 5% for freeze-dried tea extracts in an instant beverage product.

3.2 Characterization of Liquid and Lyophilized Extracts

3.2.1. Yerba Mate Composition

Both UV spectra for liquid and lyophilized samples were similar and corresponded to the typical spectrum of chlorogenic acid or its derivatives [15]. UV spectra showed a maximum absorbance at 325 nm corresponding to chlorogenic acid. Lower values were obtained for lyophilized yerba mate extracts compared to liquid ones.

Both extracts were also analyzed by HPLC, as can be observed in Figure 1, chlorogenic acid (t<sub>r</sub> = 11.92 min), caffeic acid (t<sub>r</sub> = 12.88 min), caffeine (t<sub>r</sub> = 15.36 min) and rutin (t<sub>r</sub> = 36.48 min) were identified, whereas quercetin, kaempferol and gallic acid were not detected in the analyzed samples. Also, several non-identified peaks were found. DAD spectra analysis revealed that their chemical structures have a high concordance with that of chlorogenic acid. Because of the lack of commercial standards, a tentative identification of those peaks was made according to a European patent (ES 2 267 182 T3). In the mentioned work, using HPLC-MS, peaks eluting before chlorogenic acid (t<sub>r</sub> = 6 and 12.1 min) were identified as chlorogenic acid isomers and peaks eluting after (t<sub>r</sub> =

*a* different letters indicate statistical differences between extract state ($\alpha = 0.05$), $n \geq 3$.

As well, caffeine content was very close to the values reported by Heck, Schmalko and González de Mejia [8], when studying several yerba mate samples from Argentina, Paraguay and Brazil.

3.2.2. Total Polyphenol Determination by the Folin-Ciocalteau Method

Total polyphenol content was also calculated from HPLC data (TPC<sub>HPLC</sub>) as the sum of chlorogenic acid and related compounds, rutin and caffeine peaks. Liquid and
lyophilized extracts contained 127.8 and 104.1 mg polyphenols/g yerba mate, respectively, showing a decrease of around 20% that could be attributed to the lyophilization process.

Total polyphenol contents of both liquid and lyophilized extracts are shown in Table 2. Chlorogenic and gallic acids were used as standards since the former is the major compound found in HPLC yerba mate studies [18], [20] and the latter is widely used for comparison purposes with natural polyphenol sources [21,22]. The Folin-Ciocalteau method has been widely used as reference in the determination of TPC in natural extracts. This technique often shows results numerically different to those obtained by other methods; however, relative values usually correlate well when comparing similar samples [22].

Table 2 shows that TPCFC values for lyophilized yerba mate samples were lower (p < 0.05) than those for liquid extracts. A similar trend was found for the calculated total polyphenol content by HPLC. The values obtained for liquid extracts were similar to those found by Bastos, Ishimoto, Ortiz M. Marques, Fernando Ferri and Torres [23]. Lyophilized extract samples showed similar TPCFC values (94.3 mg chlorogenic acid/g dry leaves) to values determined by Chandra and Mejía [20] and Heck, Schmalko and González de Mejía [8]. Though the lyophilization process decreased the total polyphenol content of yerba extracts (Table 1), this value was comparable to those found in liquid extracts by Dall’Orto [24] and Bravo, Goya and Lecumberri [25].

3.2.3. Antioxidant Capacity

The antioxidant capacity of pure standard compounds was determined by PCL and their contribution to the overall antioxidant activity of liquid and lyophilized extracts was evaluated. The standards were tested in a range of concentrations, including those present in the extracts. The presence of a water-soluble antioxidant leads to quantity-dependent temporal inhibition of PCL. An evaluating parameter of the curves is the duration of the lag-phase of the PCL (Figure 2). For example: chlorogenic acid is a sample with antioxidant activity and water is a blank sample. All tested substances show a linear dependence of the lag-phase on the substance quantity. Caffeine did not have suitably retarded lag-phases, necessary for performing this calculation. The lack of a proper lag-phase is not due to concentration effects, as we found that neither further dilution nor concentration generated integrable lag phases. A lower concentration of the standard chlorogenic acid was used, as compared to the other samples, in order to fit all data in the same plot (Figure 2). The overall PCL activity in decreasing order was chlorogenic acid > caffeic acid > rutin and caffeine.

The high antioxidant capacity of chlorogenic and caffeic acids showed an increasing trend with concentration (Figure 3). On the other hand, rutin and caffeine presented a much lower activity under the assayed range of concentrations. Anesini, Turner, Cogoi and Filip [19], also working in yerba, found no antioxidant activity for pure caffeine as determined by DPPH• radical method.

The major contributing polyphenols in yerba mate were chlorogenic acid and related compounds, while the rest of fractions were not considered in the following calculations, given their lower content in the extracts and/or reduced activity.

The total amount of chlorogenic acid and chlorogenic acid derivatives was 105.7 and 87.2 mg/g yerba for liquid and lyophilized extracts, respectively, as calculated from Table 1. To enable comparison with the determined standard curves (Figure 3) the amounts of 211.4 and 266.7 µg of chlorogenic acid /ml were calculated for liquid and lyophilized extracts, respectively. These values were derived after the original yerba amounts employed to prepare extracts and the dilutions carried out before PCL determinations. The estimated PCL antioxidant capacity, from chlorogenic acid curve was around 4.3 and 4.5 mg
Figure 3. Effect of concentration on the antioxidant capacity determined by PCL. Curves correspond to standard compounds and large-empty-symbols to the experimentally determined (det.) and calculated (calc.) values for liquid and lyophilized extracts.

*(g antioxidant/g DPPH•); **Results are expressed as g yerba mate/g de DPPH•;

Table 3 shows EC$_{50}$ and TEC$_{50}$ values for yerba mate extracts and standard substances. These parameters are commonly used to compare the antiradical power of different compounds [10, 11]. Brand-Williams, Cuvelier and Berset [10] found EC$_{50}$ values of 0.24 and 0.27 for the commercial antioxidants BHA or BHT and ascorbic acid, respectively. Values obtained for yerba mate extracts were higher than those for commercial antioxidants.

Atoui, Mansouri, Boskou and Kefalas [21] studied antioxidant activity of natural herbs; chamomile (matticaria recutita) and mint (mentha piperita) showed EC$_{50}$ values close to yerba mate liquid extract. In the same study, green tea, the worldwide famous infusion because of its reputed antioxidant power, presented three times higher values than those reported here for yerba mate.

Brand-Williams, Cuvelier and Berset [10] established a classification of compounds with antiradical activity depending on their reaction kinetics. These authors observed three types of behavior: 1) rapid, 2) intermediate and 3) slow kinetics, depending on the time the compounds took to reach the stationary state (less than 1 min, between 5 and 30 min and between 1 and 6 hours, respectively). Under this criterion, yerba mate extracts should be included in the second of the three groups, taking into account that they reached the steady state at about 5 min for both types of extracts. Other compounds within this group are $\delta$-tocopherol and rosmarinic acid, with EC$_{50}$ 0.25 and 0.14, respectively [10]. Although being in the same kinetic group, both compounds presented lower EC$_{50}$ values when compared to the liquid or lyophilized extract (Table 3).

With regard to the processing conditions, DPPH• assay seemed to be more specific than PCL to differentiate antioxidant capacity of similar samples. The concentration necessary to reduce the radical levels to 50% was higher in the lyophilized extract, indicating a lower antioxidant power compared with the liquid sample. Also, a
higher $T_{EC50}$ value was found for lyophilized extract compared to the liquid one (Table 3). These results are consistent with $TPC_{FC}$ and $TPC_{HPLC}$. During lyophilization the amount of some antioxidant compounds or their structures could have been modified, decreasing the antioxidant capacity of the whole sample.

3.3. Relationship between Folin-Ciocalteau and Antioxidant Activity towards DPPH• Radical

A relationship between $TPC_{FC}$ and antioxidant activity towards DPPH• was analyzed for yerba mate extracts and chlorogenic and gallic acids. Experimental data satisfactorily fitted the following regressions:

Yerba mate lyophilized extract:

$$DPPH^•r = -74.35 \times \text{Abs.FC} + 99.22 \left( R^2 = 0.9433 \right)$$

Chlorogenic acid:

$$DPPH^•r = -85.14 \times \text{Abs.FC} + 80.03 \left( R^2 = 0.8426 \right)$$

Gallic acid:

$$DPPH^•r = -197.68 \times \text{Abs.FC} + 87.73 \left( R^2 = 0.9807 \right)$$

where $DPPH^•r$ is the remaining percentage of DPPH• and Abs.FC is the absorbance corresponding to the same concentration of compounds determined by the Folin-Ciocalteau method. The values of correlation coefficients ($R^2$) show that a linearity was found between both methods for yerba mate extracts and gallic and chlorogenic acids. Residual plots confirmed the model accuracy (data not shown). The relationship between polyphenols and antioxidant activity depends on each antioxidant source [11]. For example, Atoui, Mansouri, Boskou and Kefalas [21] did not find a relationship in the case of tea and herbal infusions, but Zhao et al. [26] found a positive correlation in barley grains. Moure et al. (2001) studied different natural antioxidant substrates from residual sources and they found a parallel increase between polyphenol content and antioxidant activity in lupin seeds. However, they did not find a correlation between the mentioned methods for malt, citric or red fruit residues, since other compounds different from polyphenols are responsible for the globally observed antioxidant activity.

Figure 4 shows $DPPH^•r$ and Abs.FC values for different lyophilized extract concentrations. Correlation between both methods is valid in the linear range of the radical decreasing curve, that is, for concentrations below 0.75 mg lyophilized extract/ml. This value corresponds to the cross point of both curves. Higher amounts of antioxidant did not cause changes in $DPPH^•r$ concentration for yerba mate extracts. The same analysis was applied to the standards (chlorogenic and gallic acids) used in this work. Previously [27], a correlation between values obtained by Folin and $DPPH^•r$ methods was used when measuring the antioxidant release of encapsulated lyophilized yerba mate extract. According to Parejo, Codina, Petakis and Kefalas [28], antioxidant properties of single compounds within a group can vary markedly, so that the same levels of phenolics do not necessarily correspond to the same antioxidant responses.

Moreover, the response of phenolics in the Folin-Ciocalteau assay also depends on their chemical structure, thus, the radical-scavenging capacity of an extract could not be predicted only on the basis of its total polyphenol content [29]. Nevertheless, in the present work, the linearity found between Folin and $DPPH^•r$ techniques could help in estimating the antioxidant activity of yerba mate extracts using a simple low-cost method like Folin-Ciocalteau. This fact may allow the implementation of a simple analytical method for quality control during future industrial processing. Thus, the decrease in antioxidant activity as shown by $EC50$ values (Table 3) could be associated to changes in chlorogenic related compounds content after lyophilization since PCL inhibition assay for pure compounds revealed that no antioxidant activity could be attributed to rutin and caffeine. Recently, Anesini, Turner, Cogoi and Filip [19] also determined that caffeine did not show any scavenging activity towards $DPPH^•r$. Thus, the lower antioxidant activity should be mainly assigned to chlorogenic related compounds.

4. Conclusions

Yerba mate liquid and lyophilized extracts showed high values of polyphenol content and antioxidant activity, determined by the Folin-Ciocalteau and $DPPH^•r$ and PCL methods, respectively. The correlation found between TPC determined by Folin-Ciocalteau and antioxidant activity determined by $DPPH^•r$, allowed determining the antioxidant activity of the polyphenols simply by using the Folin-Ciocalteau method, an easier and less expensive
method than the DPPH• assay.

The lyophilization process modified the total polyphenol content and the antioxidant power of yerba mate extracts. During lyophilization, the polyphenol content decreased by 20%; this fact was confirmed by both the Folin-Ciocalteau and HPLC methods. According to HPLC analysis, the content of chlorogenic acid did not change after lyophilization. Photochemiluminescence helped to elucidate that the decrease in polyphenols content and antioxidant activity could be attributed to changes in chlorogenic related compounds during the freeze-drying process.
