ABSTRACT
Positron Emission Tomography (PET) or integrated PET/Computed Tomography (PET/CT) with $^{18}$F-Fluoro-Deoxy-Glucose ($^{18}$F-FDG) is a functional imaging modality, useful in the characterization of undetermined morphological findings, and in the staging/re-staging of a large number of malignancies. Although its use in uterine malignancies has been poorly investigated, in recent years the employment of this technique has constantly increased. In this review, we evaluate the role of PET (CT) with $^{18}$F-FDG in uterine malignancies (cervical and endometrial cancers as well as uterine sarcomas), underlying its advantages and discussing its limitations. Metabolic and anatomic information given by PET/CT with $^{18}$F-FDG could be useful in the evaluation of local and distant disease involvement at the staging, in the detection of disease recurrence, and in the evaluation of the response after chemotherapy and/or radiotherapy.

Keywords: $^{18}$F-FDG PET/CT; Uterine Malignancies; Cervical Cancer; Endometrial Cancer; Uterine Sarcomas

1. INTRODUCTION
Positron Emission Tomography (PET) or integrated PET/Computed Tomography (PET/CT) with $^{18}$F-Fluoro-Deoxy-Glucose ($^{18}$F-FDG) study is a functional, non invasive whole body examination, that allows to metabolically characterize undetermined morphological findings, stage/re-stage disease, evaluate treatment response and monitor the therapy in a large number of malignancies (lymphomas, lung, breast, colon-rectal cancer, etc). In the genital tract of women the use of PET is controversial and it is limited by the urinary excretion of the $^{18}$F-FDG, that interfere with the evaluation of uterus and vagina, and by the numerous false positive findings related to the presence of physiological tracer uptakes in the bowel, ovaries, and in the uterus itself. However, the clinical introduction of integrated PET/CT tomography, allowing the co-registration and the superimposition of anatomical and functional images and thus the exact localization of all the $^{18}$F-FDG uptakes, improved PET diagnostic accuracy [1].

The aim of the present review is to discuss the role of $^{18}$F-FDG-PET or PET/CT (PET/(CT)) exam in the uterine cervical cancer, in the endometrial adenocarcinoma and in the uterine sarcoma.

2. LITERATURE SEARCH
For this review, in the matter of the role of $^{18}$F-FDG-PET (CT) in the above mentioned gynaecological malignancies, a MEDLINE search has been performed in order to find relevant articles. For all the evaluated malignancies we included only primary studies and meta-analysis published in the English language in the last five years. We did not include case reports, and abstracts. For uterine cervical cancer we used as keywords: uterine cancer, cervical cancer, and uterine cervix carcinoma; while for endometrial cancer we used: uterine corpus carcinoma or neoplasm, and endometrial cancer. Finally, in the case of uterine sarcomas, we used as keywords uterine sarcoma, uterine carcinosarcoma, and uterine leiomiosarcoma. In all of the above mentioned cases, each keyword was always associated with Positron Emission Tomography, PET/CT, and $^{18}$F-FDG-PET/CT. Furthermore, to complete the search we look for in the bibliography of the founded studies and considered the most recent and interesting works.

3. CERVICAL CANCER
Cervical cancer is the third most common neoplasm in women. Recent data report an incidence rate of about 42,000 new cases/year in the United States and in the European Union [2,3] and 150,000 deaths/year world-
wide [4]. In the last decades, the introduction of the Papanicolaou screening test (Pap-test) has allowed an increase in the detection rate of pre-invasive lesions; in the same time the mortality due to the invasive cervical cancer has not substantially decreased [5,6].

To stage cervical cancer the International Federation of Gynaecologists and Obstetrics (FIGO) staging system is currently used [7,8]. In patients with small localized carcinomas (stage IA and IB1) radical hysterectomy or radiotherapy alone are equally recommended [9]. For large lesions and/or locally advanced cancers (stage IB2–IVA), chemo-radiotherapy is the treatment of choice [10,11]. Tumour size, parametrial tissue involvement, pelvic and/or para-aortic lymph node spread and deep invasion of nearby organs are the most important prognostic parameters at the diagnosis [12]. Patients with these unfavourable prognostic factors are at high risk of developing disease recurrence with an estimated recurrence rate ranging between 23% and 35% [13,14].

Even if the assessment of local and distant disease extension is a crucial point both in the pre- and post-treatment phases, however a standardized protocol to stage/re-stage these patients has not been established [15]. In particular, no imaging modalities are routinely used in this work up, which is based on physical examination, Pap-test, serum markers assay and surgical evaluation. Currently, the use of 18F-FDG-PET/CT in the management of patients with cervical cancer has been investigated in different settings.

3.1. Staging

The assessment of the primary lesion is actually based on the clinical examination and on morphological imaging modalities, in particular MRI. One of the crucial data is the presence of uterine parametrial invasion. In this field, despite the presence of co-registered CT images, the diagnostic performance of 18F-FDG-PET/CT is worse than MRI, due to the lack of a good spatial resolution. In the local staging of 32 primary tumours, Park et al. highlighted a higher number of false negative results at PET scan than at MRI (3 and 1 case, respectively) [9]. Probably, in stage IA or IB the amount of disease is under or at the limit of the PET system resolution and its detection can be elusive. Moreover, the interference of urinary activity, that of physiological processes (such as hormone-dependent changes in the ovaries and endometrium during the phases of menstrual cycle) and some benign pathologies (such as corpus luteum cysts, endometriosis, inflammations, menstruations, etc.) can interfere with the optimal evaluation of the primary lesion, leading to difficulties in exam interpretation [12,16]. Some of these PET limitations can be reduced with practical expedients: for example, the urinary interference can be avoided by emptying the bladder just before the start of the exam, or by the hydration and administration of diuretics, or by the continuous bladder irrigation to dilute and remove the radioactive urine. On the basis of these limitations, it is clear that, despite the on-going technical improvements, PET is still unsatisfactory in the evaluation of the primary lesion and particularly in the identification of the deep uterine tissue involvement.

On the other hand, an application of PET exam in these cases is actually under debate, i.e. the prognostic value of the primary lesion 18F-FDG uptake. The tumour 18F-FDG uptake, generally measured by the maximum Standardized Uptake Value (SUVmax), seems to be strictly related to the behaviour and to the aggressiveness of the tumour itself as in other malignancies (head and neck, lung and oesophageal cancers). In uterine cancer different authors reported an independent correlation between the cancer SUVmax and: the lymph node status, the disease response to chemo/radio therapy, the frequency of pelvic recurrence, the disease free and the overall survival [12,17-20]. In a study on 240 patients, Kidd et al. [21] confirmed the correlation between the SUVmax at the staging and the presence of lymph node metastases. Moreover, Lee and colleagues [22] observed a good correlation between SUVmax and DFS in early stages of cervical cancer. From these experiences, it seems that SUVmax could be a useful prognostic tool in this cancer too.

In the pre-treatment disease staging, the identification of nodal (loco-regional and para-aortic) and distant metastasis are crucial points, which present prognostic and therapeutic significance. In fact, in locally advanced cervical cancer the 5 year survival rate is 57%, 34% or 12%, in node negative cases, pelvic nodes metastasis or para-aortic nodes metastasis, respectively [23]. In a recent meta-analysis, the most accurate method to study lymph node involvement resulted to be the sentinel node biopsy; however, this is a (minimal) invasive procedure, that often requires the administration of anaesthetic drugs, and that could lead to some complications. Among the imaging tests, the authors of this meta-analysis affirm that PET/CT presents better accuracy than contrast enhancement (CE) CT and MRI and that it could be used to guide laparoscopic staging procedures [24]. In fact, the sensitivity of CECT and/or MRI in identifying nodal metastasis is very low. A Gynaecological Oncology Group (GOG) study reported a sensitivity of 34% in the detection of para-aortic lymph nodes by CECT [25]. Furthermore, in patients with gynaecological cancer and CECT negative for lymph node metastasis, PET/CT showed sensitivity and specificity of 50% and 83.3% respectively [25]. The good accuracy of PET and PET/CT scans in detecting lymph nodes has been established by
the meta-analysis of Havrilesky et al., that assessed a pooled sensitivity and specificity rate of 84% and 95% for para-aortic lymph nodes and 79% and 99% for pelvic lymph nodes [26]. More recently, other authors confirmed these results for PET [27-32]. Furthermore, it was evidenced an increase in the accuracy for combined PET/CT [7,25,33-36]. Finally, Yen et al., indicate that an SUVmax of para-aortic lymph nodes greater than 3.3 is a strong negative prognostic factor in patients with locally advanced disease in respect to recurrence and survival rate [36]. On the other hand as reported by several authors, the limit of PET in this field, is represented by the significant number of false negative lymph nodes. This pitfall is related to the limited spatial resolution of the tomodiagram [31,37-39]. Kitajima et al. [40] attempted to improve the accuracy of the exam performing a PET/CECT scan. They found a per patient based sensitivity, specificity, positive predictive value, negative predictive value and accuracy of 50%, 90.9%, 66.7%, 83.3% and 80%, respectively, and per lymph nodes based sensitivity specificity, positive predictive value, negative predictive value and accuracy of 51.1%, 99.8%, 85.2%, 98.9% and 98.7%, respectively. On the other hand, Kim et al. [23] advise the use of fused MRI/PET to increase the detection of lymph node metastasis. In conclusion, due to the low sensitivity, the use of PET/CT study to stage lymph nodes should be taken into account only for patients presenting important co-morbidities and/or contraindications to the surgical approach.

### 3.2. Radiotreatment Planning

Radiation treatment is indicated in a large part of these patients. The accurate definition of the treatment planning is mandatory in order to adequately radiate the tumour and to spare near critical organs. As in other malignancies, the target volume of radiation beam is currently based on morphological examinations (such as CECT and MRI), that allow high spatial resolution images with accurate anatomical definition [41]. However, this staging modality presents some limitations [42] and the adjunct of the metabolic study significantly improve the identification of the target volumes, allowing the identification of the viable part of the tumour, and improving the staging [43,44]. When PET is used, the Planning Target Volume in modified in around 20% of cases [45]. Recently Chao [46] showed the utility of PET/CT in assisting RT treatment planning of patients with potentially curable lymph node metastases. This new information together with the new radiotherapy tools (such as intensity-modulated radiation therapy) allow a decrease in the dose to surrounding healthy tissues, as well as an increase to the target [41,47-50].

### 3.3. Re-Staging

An early detection and an accurate staging of disease are crucial elements in order to plan the therapeutic strategy and to improve prognosis [51]. In asymptomatic patients previously treated for cervical cancer, the increase of serum levels of markers such as CEA, Ca19.9 and Ca125 is one of the signs of disease recurrence. However, tumour markers are non disease specific and do not give indications about the site of disease recurrence. In disease re-staging, conventional CECT and MRI are the most frequently used imaging modalities, even if some limitations should be taken into account: first of all, they are generally limited to one body district (pelvis and/or abdomen); secondly, they are often unable to identify cancer relapse in body districts which present post-surgical or post-radiotherapy scars (good sensitivity, but low specificity levels); thirdly, they are inaccurate in characterizing small lymph nodes and in detecting the peritoneal disease [52]. Therefore, as described by van der Weldt [53] the results of the above-mentioned exams are often inconclusive and equivocal, thus justifying the use of PET. In this study the 18F-FDG-PET/CT scan showed a good sensitivity and specificity: 92% and 93% respectively. Furthermore, as reported in Table 1, different authors in the recent years investigated the usefulness of PET/CT in the suspect of recurrence, and all of them showed high sensitivity and specificity levels. In fact, PET gives a metabolic characterization of the body structures independent to their anatomy, also allowing the investigation of critical regions in which anatomy has been modified [54]. Given this and due to the possibility of identifying distant metastasis, the therapeutic strategies are changed in about 25% of patients after PET exam [26,28].

As regards the follow-up, Brooks [4] demonstrated that PET/CT presents a good accuracy in detecting recurrences in both asymptomatic and symptomatic women. In his study, it was interestingly showed that the survival of women with asymptomatic recurrences was superior to the symptomatic subjects.

As regards the prognosis, the modifications of the 18F-FDG-uptake during the course of the treatment represents an important predictor of tumour response and patient’s survival [55]. Nishiyama [19] evaluated the role of PET in monitoring the neo-adjuvant therapy in patients with advanced stages of gynaecological cancers. In his study, PET showed an accuracy of 85% in predicting response to the treatment, when the SUVmax was decreased more than 65%. However, larger studies are needed to better define the PET role in this context [56].

4. ENDOMETRIAL CANCER

Endometrial cancer is a common malignant disease, being the fourth cancer in post-menopausal women. In Europe, about 1 out of 20 new cancers’ cases interests the endometrium and in the United States the incidence rate is about 40,000 new cases/year [57,58]. As in cervical cancer, the surgical-pathological FIGO staging system is used to address patients to the more appropriate treatment. Patients with FIGO stage IA and IB (involvement of less than 50% of myometrium thickness) can be treated with a tumour resection, while patients with stage IC (involvement of more than 50% of myometrium thickness) the para-aortic lymphnode dissection and the use of adjuvant chemo-radiotherapy is one of the proposed therapeutic strategy, due to the fact that this stage has a greater incidence of nodal and distant metastasis, with a worse prognosis [59]. Generally, patients with the clinical suspect of deep myometrial invasion undergo further examinations (CT or MRI), in order to assess the extra uterine disease spread.

The role of 18F-FDG-PET/CT in the management of this neoplasm is not well defined due to the lack of consistent data in the literature, and due to this reason uterine corpus cancer is not included among appropriate applications in oncology [45].

Few small studies assessed the validity of PET alone in the evaluation of primary endometrial cancer, showing good levels of sensitivity (range 83.3-96.7% [59-61]). Torizuka et al. affirmed the feasibility of PET study in the assessment of myometrial involvement, reporting a better diagnostic accuracy than MRI (86.4% versus 77.3% respectively) [59]. In fact, in this study the SUV of the tumour correlated significantly with the depth of the tumour invasion. Furthermore, the authors used SUV of the primary tumour, dichotomized to 12, in order to predict the depth of the tumour invasion. They showed that SUV < 12 correlated significantly with superficial invasion, while SUV > 12 correlated with profound invasion of the tumour. However, due to the limited spatial resolution of the PET study, a limited size of invasion could be missed, leading to false negative PET results [62]. Recently, two randomized trials showed that in early stages of endometrial cancer the routine pelvic lymphadenectomy improves the staging, furthermore this surgical staging correlated with prognosis of the patients. However, the advantage gained was only further knowledge, since no survival benefits were observed in these patients. On the contrary, women that undergo surgical staging have increase the risks of complications. Therefore, the goal of the non-invasive staging in these women would be to select those patients in whom the surgical staging could improve prognosis not only the staging [63-65]. In regard to PET/CT, Park et al. showed in a population of 53 patients weak levels of sensitivity and specificity in the staging of primary lesions (89.4 and 50.5%, respectively) and in the staging of regional lymph nodes (69.2 and 90.3%, respectively). On the other hand, high accuracy levels were reported in the detection of distant metastasis. The authors concluded that there are two main advantages of 18F-FDG-PET/CT in the preoperative assessment of endometrial cancer: the good negative predictive value in predicting lymph node metastasis, that allows avoidance of surgical staging in poor candidates for such procedure; the high accuracy in detecting distant metastasis [66]. However, again it must be reminded that in the above mentioned study, the negative predictive value (NPV) was good but not excellent (98.9% in the pelvic evaluation, decrease in 87.5% for the para-aortic nodes). Furthermore the NPV was further investigated by Signorelli [63]. It was indicated that in high risk early stages the high NPV could be useful to avoid systemic lymphadenectomy. In such cases a de-bulking surgery of the involved nodes could be sufficient. With the decrease of lymph node dimension, a progressive significant reduction of sensitivity has been observed by Kitajima et al.: 93.3% for lesions greater than 10 mm, 66.7% for lesions between 5 and 9 mm, and 16.7% for lesions smaller than 4 mm [67]. Furthermore, Inubashiri [68] observed in recent work that 18F-FDG-PET/CT cannot change the medical management of the patients if a MRI is previously performed.

As indicated by some authors, in endometrial cancer the major contribution of 18F-FDG-PET/CT could be in the early assessment of disease recurrence after therapy [60,69]. The good performance of 18F-FDG-PET/CT has been confirmed by Kitajima et al. in a recent paper including 30 patients, that showed an overall patient-based sensitivity, specificity and accuracy of 93% [70].

In conclusion, in endometrial cancer, the most relevant indications obtained by PET are: the possibility of detecting disease recurrence in asymptomatic patients presenting an increase of the Ca125 serum levels; the ability in distinguishing fibrotic tissue from viable lesions after the treatment; the metabolic definition of the radiotherapy treatment planning. Encouraging results are also available in the assessment of lymph nodes and distant metastasis during the disease staging.

5. UTERINE SARCOMAS

Uterine sarcomas are rare neoplastic diseases which represent about a 2-4% of all uterine malignancies [71]. The histology is heterogeneous, but the more represented variety are the leiomyosarcoma, the carcinosarcoma and the endometrial sarcoma. These malignancies present an extremely poor prognosis and, despite their rarity, they are responsible for a large number of deaths every year, in women with uterine cancer. As with the benign uterine leiomyoma, clinical features are represented by vaginal bleeding and pain. Therefore, during the diagnostic process, the differential diagnosis is crucial. Unfortunately, in the majority of cases this is obtained only after surgery at the histopathological examination, because morphological imaging (US and MRI) is often inconclusive.

Therapeutic options in these cancers actually include the surgery (hysterectomy) when the cancer is localized, and chemotherapy if the tumour is locally and/or distantly extended. During the follow-up about one half of Stage I cases develop a recurrence [72]. In the management of sarcomas (soft tissues and bone sarcoma), the current literature evidences discordant data on the accuracy of the imaging modality gives useful metabolic and anatomic information, and, as in the other field of oncology, it is beginning to play an important role in the management of these patients. Despite the relatively low number of studies, its usefulness in the assessment of lymph-nodal involvement at the staging, in the detection and staging of disease recurrence, and in the evaluation of the response after chemo- and radio-therapy has been proved. In fact the use of PET/CT in uterine cancer seems to be controversial. Despite numerous and rigorous study demonstrated the utility, gynecologic oncologist are not very enthusiastic of this exam. In fact, as Kizer et al. [78] demonstrated in a recent study, when 83% of them routinely order CT scan, only 28% of them routinely order PET/CT scan. Some of them believe that PET/CT does not provide useful prognostic information whereas others cause could be the difficulty to obtain third party payment from the private paying clients. It seems that the better staging of metastatic lymph nodes or distant metastases, the very good negative predictive value in early stages, the correlation of before/after treatment PET result with the overall survival, data already available, have little impact and do not convince the gynecologic oncologist. However, these data are good sources for the planning of other prospective studies that could have a greater impact.
