Received 12 March 2010; revised 9 April 2010; accepted 10 April 2010.

ABSTRACT

Objective and Case Report: In this report a female patient with the lesion diagnosed as focal semento-osseous dysplasia by histological and radiological examination on the left mandibular molar region is presented and these focal semento-osseous dysplasia lesions are reviewed according to the literature. Conclusion: Histological and radiographic examination is significant for the differential diagnosis of FCOD. Its solid nature and posterior localization ease the differential diagnosis. The treatment includes long term follow-up for asymptomatic lesions or surgical excision if a dental implant rehabilitation is planned for the affected partial edentulous region of jaw, as seen in this case.

Keywords: Oral Pathology; Focal Semento-Osseous Dysplasia

1. INTRODUCTION

Benign fibroosseous lesions are rare diseases which are characterized by replacement of healthy bone and connective tissue that transforms to cemento-osseous tissue [1]. Fibroosseous lesions can be classified in three categories as fibrous dysplasia, benign fibroosseous neoplasms and reactive lesions [2].

The term cemento-osseous dysplasia was adopted for the WHO classification in 1992 [3]. Cement like structures are mostly seen on jaws in all skeletal bones. The term cemento-osseous is used because of the difficulty in discrimination of cement and bone tissue in lesions which produce cement, bone and connective tissue. Cemento osseous dysplasias are non-neoplastic lesions and related with tooth bearing areas. This term include florid osseous dysplasia, focal cemento-osseous dysplasia and periapical cemental dysplasia [4].

Focal cemento-osseous dysplasia is accepted as most frequently seen fibroosseous pathology. FCOD is seen predominantly in African-American females, with a peak incidence in the fourth and fifth decades. FCOD can reach 1-2 cm size in dimensions and effect edentulous jaws and the tooth extraction sockets. It may be localized nearby the teeth. FCOD can cause expansion of the local bone and can be secondarily infected [2,5-7].

FCOD is mostly a fairly well defined radiolucency with a sclerotic border or a mixed radioluscent and radiopaque lesion. Histopathologically, FCOD is formed by spindle cells, bone-cement like trabeculation and connective tissue stroma. Histopathologic view varies due to the stage of the lesion. In the early stage, cellular and vascular structures are dense and surrounded by a proliferated fibrous connective tissue stroma. In the osteolytic stage cement like structures can not be seen. In the last osteosclerotic stage the lesion reveals poor cellularity, bone trabeculae and irregular cement like structures making anastomosis with each other. Fibroosseous mid-stage consists of both early and late stage characteristics [5,8].

FCOD does not require treatment and certainly not routine biopsy unless it is infected and symptomatic [7]. In this report a female patient with the lesion diagnosed as FCOD by histological and radiological examination on the left mandibular molar region is presented. Histologically, these cemento-osseous lesions undergo change from normal vascular bone into woven bone in a matrix of fibrous connective tissue. Management of the cemento-osseous dysplasia may be difficult and not very satisfactory. The lesion may persist for indefinite periods of time without causing any symptoms. For the asymptomatic patient, the best management consists of regular recall examinations with prophylaxis and reinforcement of good home hygiene care to control periodontal disease and prevent tooth loss. [9].

2. CASE REPORT

Fifty two year old female patient was referred to Ankara University, Faculty of Dentistry, Department of Oral and
Maxillofacial Surgery for prosthetic rehabilitation of extracted left premolar and molar teeth. The patient was questioned for the physiological examination and there were no recorded physiological disorder. Clinical examination revealed a complaint of a significant dull pain on the left posterior region of the mandible and any kind of pathologic changes on the alveolar mucosa of the same region was not seen. The complaints of the patient such as eating disorder and pain did not affect the comfort of patient, but caused functional problems. In radiologic examination, a radiopaque ill-defined lesion is observed on the posterior left edentulous part of the mandible. It was decided to perform an advanced radiographic examination to evaluate the lesion. Thus, panoramic and computerised tomography was performed and a 1 cm diameter lesion was identified 2-3 mm above the mandibular canal (Figures 1 and 2).

A surgical intervention was decided to exclude pain and to prepare a healthy bone for dental implant rehabilitation. The lesion was curetted in two parts. However, pathologic tissue was not easily separated from surrounding healthy bone. The histological diagnosis was FCOD and the examination revealed compact and dense cement bone like structures deposited as irregular lamellae and ill-defined borders. Based on the observation of histologic slides, the mineralised structures did not contain a lot of cells and had a low amount of intersticiel connective tissue. There was not any sign of dentin or dentin like tissue and malignancy (Figures 3 and 4). Surgical site healed uneventfully in the postoperative period. Recurrence was not observed during the follow up period of postoperative six months before the dental implant rehabilitation (Figure 5).

3. DISCUSSION

Cemento-osseous lesions are derived from periodontal ligament tissues and occurred by the same pathological process. They can be classified in three groups which are periapical cemental dysplasia, focal cemento-osseous dysplasia and florid cemento-osseous dysplasia [10]. Periapical cemental dysplasia is bilateral and generally located periapically [9]. Florid cemento-osseous dysplasia is a dysplastic form of bone and cemental tissue and restricted in jaws. In addition to this, florid osseous dysplasia can be classified as a diffuse form of periapical cemental dysplasia [11]. It is crucial for the differential diagnosis of FCOD, provided that the lesion is solid, located posteriorly on jaws and 1-2 cm in diameter.

FCODs are cystic radiolucent lesions in the early period. Luscent lytic areas replace with opaque areas in time. FCOD do not usually expand the cortical layer [8].
Figure 4. Higher magnification of histopathologic image. Note the cellularity of connective tissue. Irregular lamellae of dense cementum-bone like deposits can be easily seen (Hematoxylin-Eosin stain × 200).

Figure 5. Panoramic radiography after 6 months follow-up postoperative period.

Once they excised, recurrence is not common. However, cystic changes may take place around the lesion [4].

FCOD was first reported as ‘localized fibro-osseous cemental lesion’ by Waldro [2]. Later, it is renamed as focal cemento osseous dysplasia and its unique feature was identified by Summerlin and Tomich [5]. It is also compared with cemento-ossifying fibroma which FCOD resembles histopathologically [5]. The establishment of the exact differentiation between cemento-ossifying fibroma and FCOD was made in 1971 [7]. It is emphasized that the surgical specimen of FCOD was in fragments on histopathologic examination, unlike COF [12]. It is difficult to distinguish FCOD and ossified fibroma clinically and histopathologically. Ossified fibromas are well-demarcated and show radiolucent feature with small radiopaque calcifications. However, FCOD is usually radiopaque. Ossified fibromas can be easily separated and excised as one segment from surrounding tissues thanks to its well-demarcated border. FCOD can not be readily excised from healthy bone [6]. It is also difficult to distinguish FCOD and florid cemento-osseous dysplasia. Florid cemento-osseous dysplasia may be familial with an autosomal dominant inheritance pattern, but there are only a few examples in the literature in which the familial pattern has been confirmed [13,14]. In the present case, no familial aspects of the disease could be established. FCOD is mostly a fairly well defined radiolucency with a sclerotic border or a mixed radiolucent and radiopaque lesion. These lesions exhibit a sclerotic appearance similar to that of other lesions on conventional radiographs. Paget’s disease of the bone may also have a cotton-wool appearance. Paget’s disease is often polyostotic, involving other bones such as spine, femur, skull, pelvis and sternum and produces biochemical serum changes, such as elevated alkaline phosphate, calcium and phosphorus levels [14]. However, there is no recorded elevation of biochemical serum levels for the focal cemento-osseous lesions in the literature.

FCOD lesion reveal itself with a female predilection [15]. They are fairly well or poor defined lesions according to some authors [5,6]. However, Okhura reported that almost all of the cases treated were well defined [16]. It is considered that infections seem to occur after the exposure of cemental masses by resorption of the edentulous alveolus or by extraction of teeth whose roots are close to the lesions [17]. Infection of FCOD may induce chronic sclerosis. Furthermore, it is reported that chronic osteomyelitis could appear on radiographic examination similar to the FCOD [17]. Waldron defined FCOD as an abnormal reaction of bone to the injury due to its significant presence at extraction sites. It is also reported that FCOD lesions are localized on edentulous posterior parts of mandible [2,16]. According to Okhura, radiolucent content of radiographic appearance of FCOD is more common in younger patients whereas complete radiopacities are more prevalent in older patients [16]. In contrast to this opinion, some studies reveal complete radiopacities can occur in younger patients [18].

Summerlin and Tomich recommended follow-up for FCOD lesions for the possibility of progression to florid cemento-osseous dysplasia [5]. FCOD lesions have tendency to occur in the other quadrants of jaws, if a FCOD lesion is present [19]. Although the follow-up for
FCOD is a widely accepted entity for researchers, there is no any recommendations about the long term follow-up of these lesions [20]. It is not known whether the bone after the healing period will be adequate for the osseointegrated implants after removal of the lesion [20].

FCOD lesions have significant clinical importance due to edentulous sites requiring osseointegrated implants, though, it is accepted that a symptomatic FCOD need no treatment. As an essential matter, the introduction of the new discovered FCOD lesions is required [20].

4. CONCLUSIONS

Histological and radiographic examination is significant for the differential diagnosis of FCOD. Its solid nature and posterior localization ease the differential diagnosis. The treatment includes long term follow-up for asymptomatic lesions or surgical excision if a dental implant rehabilitation is planned for the affected partial edentulous region of jaw, as seen in this case.

FCOD is rarely diagnosed according to the literature. Thus, due to the importance of FCOD, the lesion must be included during the evaluation of intraosseous lesions.
