ABSTRACT

Obesity, especially at mid-life, is a major risk factor for atherosclerosis, insulin resistance and the metabolic syndrome, which in turn contribute to coronary artery disease (CAD), Type 2 diabetes and Alzheimer’s disease (AD). The rise in overweight and obesity in all societies is prompting intense research into the causes and effects of the condition. Obesity disrupts many body systems including glucose and lipid metabolism, circadian rhythms and liver function. It also causes or increases inflammation and oxidative stress. Within cells, the endoplasmic reticulum (ER) appears to be particularly susceptible to such metabolic disruption. Sirtuin 1 (Sirt1) and leptin have received attention recently as they are central regulatory factors for the body’s metabolic pathways which interact at particular levels, for example lipid and Abeta metabolism. This mini-review discusses recent findings concerning obesity, lipid metabolism and the role of Sirtuin 1 and how all influence the ER. A greater understanding of obesity and its effects on metabolic control systems of the body are required, to develop pharmacological, dietary and lifestyle changes that will reduce the incidence of CAD, Type 2 diabetes and AD.

Keywords: Obesity; Sirtuin 1; Alzheimer’s Disease; Cardiovascular Disease; Diabetes

1. INTRODUCTION

Obesity is associated with an increased risk for atherosclerosis, contributing to the onset of coronary artery disease. Obesity is also well-known to be associated with Type 2 diabetes, insulin resistance and hyperlipoproteinemia. In fact, obesity and the metabolic syndrome have become major public health issues as they have reached epidemic proportions in Western populations [1]. Obesity is now recognized as an important risk factor for AD and cognitive decline [2-10]. For example, in a study of 8534 individuals from the Swedish Twin Registry, it was found that both overweight and obesity at midlife increase the risk of dementia, AD, and vascular dementia [11,12], and in an 18 year follow up study of overweight women, a higher incidence of dementia (particularly AD) was found in these women relative to controls [13]. Obesity and overweight, as measured by body mass index and skin fold thickness, has been strongly associated with AD and dementia, independent of the development of diabetes and cardiovascular disorders [6].

2. OBESITY AND ADIPOSITIVITY

Obesity is defined as having a body mass (BMI) index of >30 (BMI = weight in kg/height in m²), whereas overweight is defined as having a BMI from 25 to 30. Obesity is a medical condition in which excess body fat has accumulated to such an extent that it is likely to have adverse effects on life expectancy and leads to increased health problems. Adiposity is the body fat tissue content, and as the degree of adiposity increases, the level of adiposity can be defined as being overweight or obese by measures such as the BMI.

3. MIDLIFE OBESITY

Being overweight or obese in early life or middle adult
life leads to hyperinsulinemia which may lead to diabetes later in life. Therefore the timing and the development of adiposity is critical to the understanding how it is associated with the pathogenesis of AD (Figure 1).

In a recent longitudinal study of 1149 individuals, midlife obesity was found to be a significant risk factor for AD in later life [14]. Abnormally high levels of the Abeta peptide are believed to be involved in AD pathogenesis, and in our own recent studies, we have found a strong positive correlation between body fat and blood plasma Abeta levels in cognitively normal individuals aged between 23 to 65 [15].

4. DIET AND RISK OF ALZHEIMER’S DISEASE

Epidemiological studies have shown that people of similar ethnic origins yet living in different environments can have significantly different risks of dementia [16,17]. Nigerians living in Africa have a much lower incidence of AD when compared with African Americans living in the US [16]. Similar results were obtained with Japanese people living in Japan when compared with Japanese Americans living in the US [17]. These differences were believed to be mostly due to dietary differences. Diet and dietary fat intake are now considered particularly important when comparing the lifestyles of populations screened for AD [18]. In support of obesity and caloric intake influencing AD risk, for example, one study has found that the more saturated fat consumed in a meal the greater the risk for developing AD and senile dementia [19]. In other studies of humans and other animals, it has been found that feeding diets high in saturated fats results in learning and memory impairments. High caloric intake of saturated fat has also been associated with greater cerebral Abeta amyloid deposition [19]. In contrast diets containing chronically high levels of polyunsaturated fatty acids result in better learning when compared with diets containing saturated fat [20].

Cholesteryl esters can be hydrolysed in lysosomes following which fatty acids become available for oxidative metabolism, in particular to carbon dioxide [21]. As a result, the metabolism of dietary lipids can be assessed using a stable isotope breath test [21] and using such a test, the clearance and metabolism of cholesterol-rich dietary lipoproteins in obese individuals has been found to be markedly lower than normal, indicating that the ingested fat was poorly cleared and metabolised from the blood plasma. Obese individuals have high triglyceride levels and low HDL levels with an increase in small LDL particles [22,23]. In animal models of AD, strong correlations between high fat/high cholesterol diets and increases in brain Abeta levels and HDL cholesterol levels and lower LDL cholesterol levels have been shown. For example, increased cerebral Abeta deposition as well as increased memory impairment has been shown in AD model transgenic mice fed high fat diets, and although exercise [24] and environmental enrichment [25] have been shown to reverse these effects to some extent, when translating to clinical situations, one major recommendation would always be to reduce saturated fat intake. Longitudinal studies have shown that people with an overall lower calorie intake also have a reduced incidence of AD later in life [13].

In obese individuals, there are several abnormalities in free fatty acid (FFA) metabolism [26,27]. There is an increase in FFA release from adipose tissue to the blood plasma which impairs the uptake of glucose by muscle
For example, AD-model mouse studies have shown that inflammatory changes that are linked to age and obesity [35,36]. Increased insulin levels are known to increase the levels of Abeta and inflammation, which are associated with an increased risk of Alzheimer’s disease. High insulin levels together with obesity can lead to increases in insulin activity and reduced brain insulin levels. Insulin resistance together with obesity can lead to increases in insulin completely consuming insulin-degrading enzyme (IDE) activity–IDE can degrade both insulin and Abeta but has a preference for insulin thus resulting in elevated Abeta [38]. Preventing or correcting insulin abnormalities may reduce the risk of age related memory impairment and AD.

High fat diets are known to interfere with glucose tolerance and insulin sensitivity and yet such detrimental effects depend greatly on the type of fat consumed [39-41]: saturated and trans-fatty acids increase insulin resistance whereas mono- and polyunsaturated fats decrease resistance and protect against the disease.

7. SIRTUIN 1

The sirtuin proteins, also known as silent information regulators, are class III histone deacetylases (HDAC). Sirtuin 2 was the first to be identified: it was found to be a mediator of replicative lifespan in budding yeast. It was then shown to modulate longevity in worms and flies. These protective actions are believed to result from the beneficial regulation of stress management and energy homeostasis [42-56]. Sirtuins are now known to regulate several cell functions by deacetylating both histone and non-histone targets.

The mammalian homologue, Sirtuin 1 (Sirt1), seems to have evolved complex systemic roles in cardiac function, DNA repair and genomic stability. Sirt1 has been shown to play a central role in metabolic homeostasis. It is involved in gluconeogenesis in the liver, fat mobilisation from white adipose tissue, cholesterol metabolism, insulin secretion from the pancreas and energy metabolism in general [57]. For example, Sirt1 deacetylates and activates the transcriptional co-activator PGC1-alpha and the transcription factor FoxO1 in the liver, to promote gluconeogenesis. In adipose tissue, Sirt1 triggers fat mobilisation by inhibiting peroxisome proliferator-activated receptor gamma (PPAR-gamma), and in the pancreas, Sirt1 repression of the uncoupling protein 2 (UCP2) increases insulin secretion [58]. Sirt1 also influences mitochondrial biogenesis, inflammation (cytokine release) and amyloidosis [42-56].

Caloric restriction has been shown to extend life span. In fact, it has been shown to extend the median and maximum life span of numerous organisms including yeast, flies, worms, fish, and rodents and mammals. It is now believed that this may be mediated partly due to the increase in Sirt1 activity which is induced by caloric restriction. For example, increased Sirt1 activity mediates mitochondrial biogenesis, which in turn may reduce the production of reactive oxygen species, a possible cause of aging and AD pathogenesis [59]. The involvement of Sirt1 in insulin regulation as well as cholesterol, fatty acid and glucose homeostasis has been linked to obesity, diabetes and cardiovascular disease. As these diseases are all thought to increase risk of AD, this provides further reason to believe that activating Sirt1 by caloric restriction may reduce the risk of AD (Figure 2) [60].
The concept that diet can regulate adipocyte plasma leptin (16 kda protein) as well as Sirt1 levels is supported by reports that high fat diets can lead to leptin resistance and low Sirt1 levels in rats and humans [57,61-64]. Brain Sirt1 expression is increased by caloric restriction and fasting has been shown to increase brain Sirt1 protein content specifically in the hypothalamus. It also appears that the effect of Sirt1 on energy balance is mediated through central melanocortin signalling [58].

Recent studies suggest a functional relevance of SIRT1 in normal brain physiology, neurogenesis and neurological function [42-56]. In one important study for example, Sirt1 was found to downregulate micro-RNA known as miR-134. MiR-134 has been shown to down-regulate cAMP response binding protein (CREB) and brain-derived neurotrophic factor (BDNF), thus reducing synaptic plasticity. Sirt1 can prevent this miR-134-induced downregulation, thereby promoting synaptic plasticity [53]. Since 2005, miRNAs have been linked to complex metabolic processes in mammals, and changes to miRNAs can occur in many metabolic abnormalities and disease conditions. For example obesity, hyperlipidemia (elevated levels of blood lipids), and insulin resistance have been shown to be associated with aberrant expression of multiple essential miRNAs in pancreatic islets of Langerhans and peripheral tissues, including adipose tissue. Furthermore, in obese patients and experimental models of obesity such as 3T3-L1 preadipocytes and adipocytes from leptin deficient mice (ob/ob: mouse model of insulin resistance and obesity) and diet-induced obese mice, miRNAs normally induced during adipogenesis are down-regulated. In particular, miR-143, miR-103 and miR-107, known to regulate adipocyte differentiation, are down-regulated in the ob/ob mice, possibly through an inflammatory pathway [65].

8. SIRTUIN 1 AND THE AMYLOID PRECURSOR PROTEIN (APP) OF ALZHEIMER’S DISEASE

The maintenance of Sirt1 expression by calorie restriction has the effect of regulating lipid metabolism and energy expenditure, which in turn helps regulate the production of many other proteins [54,55,57,66]. In obesity however, Sirt1 levels are reduced and increased plasma Abeta, leptin and body fat have all been shown to correlate with increased adipose tissue size (AT). It has also been shown that Abeta precursor protein (APP) production is upregulated in adipocytes, and that plasma Abeta levels correlate with these increased levels of APP [67]. The increased plasma Abeta is proposed to be due to obesity influencing peripheral Abeta clearance, as obesity-in-duced Sirt1 dysregulation is strongly associated with liver steatosis and decreased Aβ clearance by the liver [15,33,57,66-69]. Under conditions of calorie restriction on the other hand, Aβ content in the brain is attenuated, and this effect can be reproduced in mouse neurons in vitro by manipulating cellular SIRT1 expression/activity, ultimately promoting the nonamyloidogenic α-secretase processing of the APP, which precludes the generation of Abeta [70]. In particular, the over-expression of SIRT1 in the hippocampus has been shown to provide protection against neurodegeneration in a mouse model of Alzheimer’s disease [71], and the over-expression of SIRT1 in the brains of AD-model transgenic mice has been shown to reduce brain Abeta production and amyloid deposition in these mice, due to the induction of the α-secretase enzyme ADAM-10 [72]. In the arcuate nucleus of the hypothalamus, there are two types of neurons that play vital roles in regulating feeding and energy expenditure: the anorexigenic proopiomelanocortin (POMC) neurons and
differences between people and why some individuals may be more susceptible than others to obesity and related metabolic disturbances.

9. OBESITY, THE ENDOPLASMIC RETICULUM AND ALZHEIMER’S DISEASE

Common medical conditions that can occur in middle age, such as diabetes, visceral obesity, and atherosclerosis cause considerable stress to the body. Obesity and atherosclerosis are regarded as states of chronic low-grade inflammation. At the cellular level, inflammatory mediators and lipid accumulation can evoke chronic stress, in particular affecting the endoplasmic reticulum (ER). It has recently been shown that the ER responds to metabolic stress through a well-coordinated molecular response. This involves the transcriptional activation of a variety of genes, the attenuation of protein synthesis, the degradation of ER-localised misfolded proteins, and sometimes the onset of apoptosis [83]. Disturbances in liver metabolism are known to be key components in the development of fatty liver, insulin resistance, and atherosclerosis. It has been shown that SIRT1 helps to regulate lipid homeostasis by positively regulating peroxisome proliferators-activated receptor alpha (PPARalpha), a nuclear receptor that mediates the adaptive response to fasting and starvation. This was demonstrated in liver-specific SIRT1 knockout mice, which when challenged with a high fat diet, developed hepatic steatosis, hepatic inflammation, and endoplasmic reticulum stress [46]. In these mice, PPARalpha signalling was shown to be impaired and fatty acid beta-oxidation was decreased. In other studies, the overexpression of SIRT1 in the liver of diet-induced insulin-resistant low-density lipoprotein receptor-deficient mice and of genetically obese ob/ob mice attenuates hepatic steatosis and ameliorates systemic insulin resistance. These beneficial effects were associated with decreased mammalian target of rapamycin complex 1 (mTORC1) activity, inhibited unfolded protein response (UPR) and enhanced insulin receptor signaling in the liver, leading to decreased hepatic gluconeogenesis and improved glucose tolerance. These studies suggest that SIRT1 acts as a negative regulator of UPR signalling in Type II diabetes, and supports the concept that SIRT1 can attenuate hepatic steatosis, reduce insulin resistance, and restore glucose homeostasis, largely through the inhibition of mTORC1 and ER stress [84]. In other recent studies of SIRT1 and diabetes, SIRT1 in HepG2 cells has been shown to regulate ER stress by increasing expression of oxygen-related protein 150 (ORP150), an inducible ER protein thought to be a molecular chaperone involved in Ca²⁺ metabolism, again supporting the concept that SIRT1 can ameliorate insulin resistance via the regulation of ER stress [85].
10. CONCLUSIONS

The potential influence of associations between obesity and Alzheimer’s disease pathogenesis has been of great interest in recent research. High caloric intake and the consumption of a diet rich in saturated fat have both been associated with obesity, Type 2 diabetes, cardiovascular disease and Alzheimer’s disease. Sirt1 appears to play a central role in many metabolic changes that have been implicated in many of these conditions, as well as in AD pathogenesis. Recent studies of Sirt1 and ER function suggest Sirt1 provides considerable protection against metabolic stress via ER regulation.

Several studies have suggested that in early to mid-adult life, exercise and dietary interventions [86,87] such as calorie restriction may prevent obesity as well as reduce or prevent amyloid deposition in the brain, due to the resultant chronic activation of Sirt1 in tissues such as the brain and the liver. When considering diet, omega-3 fatty acids are important for brain development, and fish consumption has been associated with decreased cognitive deficits and a reduced risk for AD [88,89]. A diet low in saturated fats and cholesterol, yet rich in fruit, vegetables, and omega-3 fatty acids may provide essential micronutrients and antioxidants. Pharmaceutical treatments and/or other therapies centered around Sirt1 regulation might provide promising therapies in the treatment of metabolic diseases including obesity. Studies have already provided support for this theory—for example, the activation of Sirt1 by the polyphenol resveratrol and several synthetic pharmacologic activators has been shown to protect against high-fat diet induced obesity and other metabolic derangements. This is supported by studies which have found that transgenic mice over-expressing SIRT1 are leaner than controls, have a higher metabolism, and have lower serum levels of cholesterol, insulin, and glucose. Thus, calorie restriction, regular exercise, and/or drug treatment in obesity or other disease state may maintain or restore normal SIRT1 gene function. The evidence suggests that this would ultimately stabilise lipid metabolism and cause significant weight loss, reduce obesity and related disorders, as well as reduce or delay the development of Alzheimer’s disease.
