Abstract

We investigated respiratory tumor motion in lung stereotactic body radiotherapy (SBRT) with use of the “Air-Bag System”. 114 patients underwent four-dimensional (4D) computed tomography (CT) from October 2010 to April 2012. Gross tumor volume (GTV) was 8.1 ± 11.0 cc (range 0.3 - 77.5 cc). The tumor site was the upper and middle lobes in 62 cases, and lower lobe in 52 cases. The Air-Bag System™ consists of an inelastic air bag connected to a second smaller elastic air bag. The inelastic air bag is placed between the patient’s body surface and a HipFix and is secured by pressure adjustment via the elastic air bag. To assess respiratory tumor motion, the centroid of the tumor position is measured in the left-right, anterior-posterior, and caudal-cranial directions using the iPlan RT Dose™ treatment planning system. Respiratory tumor motion vector for patients with upper/middle and lower lobe tumors was 3.0 ± 2.2 mm (range, 0.4 - 11.7 mm) and 6.5 ± 4.6 mm (range, 0.4 - 22.0 mm) respectively, with this difference being significant (p < 0.05). Mean respiratory tumor motion for all patients was 0.9 ± 0.6 mm (range, 0.1 - 3.6 mm) in the left-right direction, 1.5 ± 1.1 mm (range, 0.1 - 5.7 mm) in the anterior-posterior direction, 4.1 ± 4.0 mm (range, 0.1 - 21.4 mm) in the caudal-cranial direction, and 4.7 ± 4.0 mm (range, 0.4 - 22.0 mm) overall. The Air-Bag System is expected to be provided an effective reduction in the motion of lung tumors.

1. Introduction

Intrafraction motion is an important issue in the era of image-guided radiotherapy. Intrafraction motion can be caused by the respiratory, skeletal muscular, cardiac, and gastrointestinal systems [1]. Lung tumor motion is related to breathing, which produces the greatest movement in the caudal-cranial direction [1]-[4]. Daily patient set-up should take account of internal variability in tumor position independently of bony anatomy or the external stereotactic system [5]. To achieve this, an internal margin should be added around the clinical target volume (CTV) to account for respiratory tumor motion [6]. However, this margin results in an increased dose to the normal tissue, which increases the risk of normal tissue toxicity and limits dose-escalation, and in turn leads to a higher probability of radiation pneumonitis [7]. Methods to reduce the margin include delivery techniques such as respiratory gating, active breathing control, real-time tracking, and voluntary breath holding [8], but these require a longer time for beam delivery and are more difficult for old patients, who must maintain normal breathing over the delivery time. We consider that respiratory tumor motion is best controlled under free breathing using an abdominal compression system to suppress respiratory tumor motion.

Abdominal compression has been widely used to minimize respiratory-associated tumor motion in lung stereotactic body radiotherapy (SBRT). One such system is the Stereotactic Body Frame (Elekta, Crawley, UK), which can be used in combination with an abdominal pressure board [9]. However, this system is not comfortable for the patient. We have therefore used the Air-Bag System™ (Niigata Kiden Ltd., Niigata, Japan), which uses abdominal compression to suppress respiratory tumor motion.

The purpose of this study was to investigate respiratory tumor motion using the Air-Bag System.

2. Materials and Methods

2.1. Patient Characteristics

114 patients with localized lung tumors suitable for SBRT were enrolled between October 2010 and April 2012. Patient characteristics are shown in Table 1. Gross tumor volume (GTV) and patient age did not significantly differ between patients with tumors in the upper/middle and lower lobes.

2.2. Principle of the Air-Bag System

The Air-Bag System consists of an inelastic air bag connected to a second smaller elastic air bag, air flow sensor and air supply pump (Figure 1). The length and width of the inelastic air bag are 250 and 460 mm, respectively. Figure 2 shows the process of acquiring the respiratory wave using the Air-Bag System. The inelastic air bag is placed between the patient’s body and the stereotactic fixation frame. The air bag is then inflated using an air supply pump. The two bags are interconnected. An air flow meter device located between the two air bags measures “air flow” back and forth between the two bags. These data are processed using a computer and translated to provide a highly accurate respiratory motion curve. This curve is displayed as a swinging decoy marker on the computer screen to allow the infrared camera of the Real-Time Position Management System™ (RPM) (Varian Medical Systems, Palo Alto, CA) to capture the breathing pattern (Figure 3). The Air-Bag System can be easily and immediately connected in a plug-and-play structure, and can be interfaced on use with the RPM system’s infrared camera. Thanks to this, the Air-Bag System does not require specific patient data, treatment data, or input of any particular information from other devices, and can be easily integrated with the existing

RPM System infrared camera. Further, four-dimensional (4D)-Computed Tomography (CT) can be performed using the existing RPM system with the swinging decoy.

2.3. Treatment Procedure

The patient is placed in the supine position on an evacuated Vac-Lok\textsuperscript{TM} immobilization device (CIVCO Medical Solutions, South Kalona, Iowa, USA) with the arms above the head (Figure 4(a)). The Vac-Lok\textsuperscript{TM} is evacuated using a vacuum pump so that it molds to the patient’s posterior body surface. HipFix (CIVCO Medical Solutions, USA) is attached to the sides of the Vac-Lok\textsuperscript{TM} to mold the patient’s body surface to the level of the abdomen or thorax. The inelastic air bag is placed between the patient’s body surface and the HipFix\textsuperscript{TM} and secured by pressure adjustment via the elastic air bag (Figure 4(b), Figure 4(c) and Figure 5). The air bag can be inflated by injection of 2000 cc of air using an air supply pump. If a patient experiences excessive air pressure, the volume of air can be reduced. The flow of air displayed on the sensor screen reflects the breathing of the patient, and this information is then used as output towards the RPM device.

As a routine procedure in the planning of stereotactic radiotherapy, a whole chest 3D-CT series was obtained under free breathing using the Air-Bag System, with acquisition on a 4-slice Brightspeed QX/i\textsuperscript{TM} scanner (GE Medical Systems, Waukesha, WI). Tumor shape, volume, and position at different phases of the breathing cycle were more accurately determined using 4D-CT. The CT images had a slice thickness of 2.5 mm with a gantry rotation time of 1.0 second. Respective images were tagged with the corresponding phase of the respiratory cycle and then sent to the Advantage Workstation\textsuperscript{TM} (GE Medical Systems) using the Advantage 4D-CT software. The 4D datasets were categorized into four phases of the respiratory cycle of 0%, 25%, 50%, and 75%, with 0% representing maximum inspiration.

Image registration was fused on the bony anatomy using the iPlan RT image ver 4.1.1\textsuperscript{TM} treatment planning system (Brainlab, Munich, Germany). The GTV was contoured by a single physician on each axial slice. The window width and level used to define the tumor target were 1200 HU and \textasciitilde 400 HU, respectively. The CTV was defined as the same volume as the GTV in almost all cases. The internal target volume (ITV) was the sum of the GTV positions in all respiratory phases.
Figure 4. Use of the Air-bag system. (a) The patient lies down in a supine position. (b) The inelastic air bag is placed in the same position as the patient abdomen. (c) The inelastic air bag is placed between patient’s body surface and the HipFix device, which is fixed on the couch.

Figure 5. Patient lies down in a supine position with the Air-Bag System.

The planning target volume (PTV) was generated by adding a uniform margin of 8 mm to the ITV to account for set-up uncertainties and mechanical inaccuracy. The treatment fields were conformed around the PTV. A leaf margin of 2 mm was added to the PTV, and the isocenter was positioned in the center of the PTV. Treatment plan characteristics have been described previously [10].

2.4. Data Analysis

Respiratory tumor motion was evaluated using the 4D-CT images, and measured from the displacement of the centroid of the GTV in the different phases. The geometric centroid of each GTV volume was determined in iplan
RT Dose. Respiratory tumor motion was classified into three different directions, with the X (left-right), Y (anterior-posterior) and Z (caudal-cranial) positions determined for each phase. Motion was then defined as the absolute difference between the maximum coordinate and minimum coordinate of each phase and combined in quadrature to obtain the magnitude of the three-dimensional (3D) vector, calculated by:

\[ \sqrt{X^2 + Y^2 + Z^2} \]

Differences in the upper/middle and lower lobes were analyzed using the Student unpaired t-test, with p-values less than 0.05 considered statistically significant. The analyzed data were displayed as the mean ± standard deviation with ranges in parentheses among the 114 clinical plans.

3. Results

Figure 6 shows plots of respiratory tumor motion of the upper/middle and lower lobes. Figure 7 shows the mean respiratory tumor motion of the upper/middle and lower lobes. Respiratory tumor motion in patients with tumors in the upper/middle and lower lobes was greatest in the caudal-cranial direction, at 2.3 ± 2.2 mm (range, 0.1 - 11.3 mm) and 6.3 ± 4.6 mm (range, 0.3 - 21.4 mm) (p < 0.05), respectively. Respiratory tumor motion in the left-right direction with upper/middle and lower lobe tumors was 0.9 ± 0.7 mm (range, 0.1 - 3.6 mm) and 0.9 ± 0.6 mm (range, 0.1 - 2.9 mm) (p = 0.74), respectively, while that in the anterior-posterior direction was 1.5 ± 1.0 mm (range, 0.1 - 5.7 mm) and 1.5 ± 1.2 mm (range, 0.1 - 5.1 mm) (p = 0.39), respectively. Respiratory tumor motion vector for patients with upper/middle and lower lobe tumors was 3.0 ± 2.2 mm (range, 0.4 - 11.7 mm) and 6.5 ± 4.6 mm (range, 0.4 - 22.0 mm), respectively, with this difference being significant (p < 0.05). Mean respiratory tumor motion for all patients was 0.9 ± 0.6 mm (range, 0.1 - 3.6 mm) in the left-right direction, 1.5 ± 1.1 mm (range, 0.1 - 5.7 mm) in the anterior-posterior direction, 4.1 ± 4.0 mm (range, 0.1 - 21.4 mm) in the caudal-cranial direction, and 4.7 ± 4.0 mm (range, 0.4 - 22.0 mm) overall. Respiratory tumor motion of more than 20 mm was seen in one patient, who had a lower lobe tumor.

4. Discussions

This study demonstrates the benefits of the Air-Bag System in respiratory tumor motion using abdominal compression to produce a highly efficient decrease in breathing-induced tumor motion. Our results indicate that average respiratory tumor motion with the Air-Bag System was 3.0 and 6.5 mm for upper/middle and lower lesions, respectively. Respiratory tumor motion range in the upper/middle lobe along the cranio-caudal direction was significantly smaller than that in the lower lobe. Respiratory tumor motion of more than 20 mm was seen in one patient, who had a lower lobe tumor.
one patient, with a lower lobe tumor. This decrease in organ motion is achieved by limiting diaphragmatic movement and reducing breathing volume. Respiratory tumor motion is generally 2 cm, and is larger in the cranio-caudal direction, where maximum motion of 3 - 4 cm is seen when the tumor is located just above the diaphragm [1].

Several solutions to account for respiratory tumor motion have been developed, including deep inspiration breath holding [11], the gating technique [8], and abdominal compression [9]. In deep inspiration breath holding, the therapist coaches the patient in achieving a reproducible deep inhalation breath hold during simulation and treatment. After holding the breath for a long period, however, the patient may tend to take deeper breaths, which may in turn affect the reproducibility of tumor position. In the gating technique, the therapist focuses on the gating system monitor and is prepared to intervene if the patient’s breathing is very irregular or differs from that in simulation. These techniques result in a longer treatment time and the time and effort of additional staff. Forced shallow breathing uses abdominal compression, such as via the Stereotactic Body Frame system. Negoro et al. reported that abdominal pressure using the Stereotactic Body Frame reduced respiratory tumor motion significantly, from a range of 8 to 20 mm to a range of 2 to 11 mm [9]. Liu et al. reported that average tumor motion in the left-right, anterior-posterior and caudal-cranial directions was 1.2, 1.6, and 14.7 mm for lower lung tumors using an abdominal compression plate, respectively [12]. However, the stereotactic body frame system can obstruct the treatment beam arrangement, and beam attenuation caused by the body frame must be accounted for in the planning process [13]. In contrast, the Air-Bag System allows the beam to be arranged freely and seldom results in beam attenuation. Accordingly, it can also be used in radiotherapy for liver cancer. Ko et al. have reported a similar device, the “Air-injected blanket” (AIB), which provided a mean decrease in respira-
tory tumor motion in the caudal-cranial and anterior-posterior directions from 2.6 to 0.7 cm and 2.7 to 1.3 cm, respectively [14]. Application of pressure to the abdomen decreases respiratory tumor motion by both reducing diaphragm motion and limiting normal respiration. Given that it is placed between the entire surface of the patient’s body and a HipFix™, we speculate that the Air-Bag System contributes to tumor position reproducibility primarily as an immobilization device.

Breathing control is critical to ensuring the accuracy of stereotactic irradiation in lung cancer patients. Breathing patterns can vary in magnitude, period and regularity during treatment sessions [15]. Onishi et al. developed the Abches (Apex Medical, Tokyo, Japan) system for respiration monitoring. This system reports respiratory tumor motion and enables respiration control with high accuracy and reproducibility, and thereby facilitates high-precision radiotherapy [16]. Visual or audiovisual biofeedback has been demonstrated to reduce breathing variation in mean cycle-to-cycle position, displacement, and period [17] [18]. The RPM system monitors the vertical displacement of two reflective markers attached to the patient’s abdomen. Precise capture of the movement of the infrared reflective marker box using the infrared camera of RPM is difficult, however, as the results tend to be of relatively small amplitude and thus of limited quality. In our experience, placement of an infrared reflective plastic box on the abdomen as an external fiducial marker is inherently unstable. In contrast, combined use of the RPM and Air-Bag Systems allows the measurement of breathing patterns. This combination uses an exhaustive yet simplified evaluation of the three dimensional variation of movement of the chest and abdomen through respiration to provide a highly reliable motion signal, which greatly increases the reliability of the overall RPM system once the signal is fed to the infrared camera.

The most important muscle of inhalation is the diaphragm. Diaphragm motion likely has a close relationship with the tumor motion for lower lobe lung tumors, in which mechanical coupling between the tumor and diaphragm would be strongest. Eccles et al. reported that abdominal compression reduces three-dimensional liver tumor motion in most patients [19]. Abdominal compression with the Air-Bag System reduces movement of the diaphragm, which in turn decreases intrathoracic organ motion and leads to a reduction of the ITV, resulting in a decreased dose to the normal lung. Comparative studies with and without the Air-Bag System are needed to verify whether compression is also useful in reducing respiratory tumor motion.

5. Conclusion
The Air-Bag System is expected to provide both an effective reduction in the motion of lung tumors and a high quality, real-time breathing measurement signal. Our results support the clinical acceptability of treatment planning based on the Air-Bag System.
