ABSTRACT

Background: The objective of this study was to assess the additional yield of US and CT following a “negative” initial MIBI-scintigraphy (MIBI) in patients with primary hyperparathyroidism. Methods: Prospective data were collected regarding 100 consecutive patients, preferentially undergoing a minimally invasive parathyroidectomy (MIP). MIBI was the initial imaging study for localizing a solitary adenoma, followed by US and CT (US/CT) in “MIBI-negative”-patients. Results: Surgery led to normocalcemia in 98 patients (98%) after one operation. Overall 97 patients had solitary parathyroid disease while three patients had multiglandular disease. The sensitivity of imaging increased from 74% for MIBI alone to 92% following subsequent US/CT in “MIBI-negative”-patients. The positive predictive value of a “positive” MIBI was 96% and 76% of a positive US/CT following negative MIBI. The proportion of patients who underwent successful MIP increased from 60 to 72%. Conclusions: MIBI and the combination of US and CT are complementary imaging studies. Additional localization studies after a negative sestamibi scan enhances the number of patients with primary hyperparathyroidism profiting from a minimally invasive approach.

1. Introduction

Primary hyperparathyroidism (PHPT) affects 0.3% of the general population and the incidence is 21.6 cases per 100,000 person-years [1,2]. The incidence rises with age and women are affected twice as much as men. In the last two decades minimally invasive parathyroidectomy (MIP) has gradually replaced conventional neck exploration (CNE) as the surgical procedure of choice in patients with sporadic primary hyperparathyroidism (pHPT). MIP reduces the extent of surgical dissection, operative time, hospital stay and perioperative morbidity, [3-7] while cure rates are comparable to the results of CNE [8]. Preoperative parathyroid adenoma localization and intra-operative PTH-assessment (IOPTH) both contributed to this success [9,10].

Correct preoperative imaging of a solitary adenoma is a prerequisite for a focused surgical approach. Preoperative imaging strategies varies. Te-99-sestamibi scintigraphy (MIBI) is most commonly used and frequently advocated as the initial investigation [11]. Its sensitivity is reported as high as 71% - 93% [12-17]. While MIBI identifies a hyperfunctional parathyroid gland (PG), ultrasonography (US) and CT-scanning (CT) of the neck detect an enlarged PG. At present single-photon emission computed tomography (SPECT) and the fusion of SPECT and CT images (SPECT/CT) is gaining importance, combining qualities that aim to detect a physiological abnormality and determine its exact anatomical localization [18].

In order to maximize the potential number of candidates for minimally invasive parathyroidectomy we routinely use MIBI as a first investigational step, followed by CT and US (CT/US) when MIBI is “negative”, in patients with sporadic pHPT. In a prospective cohort study, the additional yield of CT/US following a “negative” MIBI was evaluated.

2. Methods

From January 2000 until September 2010 data were collected prospectively of all patients operated for pHPT in the Diakonessenhuis Hospital Utrecht. Patients with familial hyperparathyroidism (MEN-syndromes), patients previously operated for pHPT and lithium induced hypoparathyroidism were excluded. In all patients the diagnosis was established biochemically by: an increased serum calcium level (>10.20 mg/dL) combined with an
increased (>70 pg/mL) or a not suppressed plasma PTH level, or an increased renal calcium excretion combined with an elevated PTH level.

Planar parathyroid scintigraphy using $^{99m}$Tc-sestamibi (MIBI) was routinely done as a first investigational step for localization of a solitary adenoma. When MIBI scanning revealed no adenoma both US (13 MHz linear transducer; Acuson Antares, Siemens) and CT (16 slice; Somatom, Siemens) using a slice thickness of 3 mm interval of the neck were done (CT/US). All patients were operated under general anaesthesia by the same surgeon. When at least one investigational procedure suggested a solitary adenoma a minimal invasive operation was started with a small incision that could be converted into a Kochers incision when necessary. A MIP was started as a 2-cm-long transverse incision at the medial border of the sternocleidomastoid muscle and continued as a “lateral approach” [19]. Concomitant thyroid pathology, suspicion of parathyroid malignancy and large size of a parathyroid adenoma were reasons for a unilateral exploration through a 4 cm Kochers incision, without exploration of the contralateral glands.

After removal of a preoperatively identified abnormal gland, the operation was ended, without further exploration of the neck and identifying the other parathyroid glands. When the intraoperative findings were not consistent with the preoperative imaging, MIP was converted to a CNE. IOPTH sampling was not available. Intraoperative frozen section analysis was used to confirm the parathyroid origin of excised tissue specimens. Gland weight was determined to reveal a possible relation between weight and MIBI sensitivity. Patients were cured when serum calcium and PTH levels normalized postoperatively and remained normal at least six months after definitive surgery.

### Statistical Analysis

Since all imaging studies aimed to localise a solitary adenoma, a positive imaging result was defined as the visualisation of a single parathyroid abnormality. Patients were classified as having single gland disease when they were cured after removal of one abnormal PG. A contingency ($2 \times 2$) table was made relating the operative findings to the preoperative predicted localization. **Sensitivity** of imaging studies aiming to detect solitary adenoma was defined as the proportion of patients with solitary gland disease (solitary adenoma and carcinoma) in whom a solitary adenoma was identified and correctly localized by preoperative imaging (no effort was made to distinguish between superior or inferior glands).

**Positive predictive value** (PPV) was defined as the proportion of all patients with a positive imaging study in whom the result had correctly identified and localized single gland disease.

The overall success rate of the preoperative imaging work-up was defined as the proportion of all patients in whom a solitary adenoma was correctly identified, *i.e.* in accordance with the outcome of the operation.

The additional yield of US/CT following a “negative” MIBI was addressed by evaluating its effect on the overall sensitivity of the preoperative imaging work-up, as well as the positive predictive value of US/CT as compared to MIBI alone and the effect on the proportion of patients who underwent successful minimal invasive surgery.

### 3. Results

One hundred consecutive patients underwent parathyroid surgery for non-familial pHPT. There were 23 men and 77 women, with a median age of 60 years (range 25 - 85). Patient characteristics are listed in Table 1.

Preoperative MIBI showed unilateral uptake consistent with a solitary adenoma in 75 of 100 patients (75%) (Figure 1). In one patient scintigraphy suggested MGD. In the other 24 patients additional US/CT suggested the presence of a solitary adenoma in 21 patients. Overall, scintigraphy, followed by CT/US identified 96 patients with a presumed solitary adenoma.

MIP was the planned operative approach in 91 out of the 96 patients with visualized solitary gland disease. In 17 patients (18%) MIP was converted to a CNE due to insufficient exposure in eleven patients and preoperative imaging not being consistent with the intraoperative findings in six. The success rate of the first operation was 98 percent. As a result of the first operative procedure one enlarged PG was removed in 97 patients, two or more enlarged PG were found in two patients, and no

A solitary adenoma was found in one patient. Hypercalcemia persisted in two patients (2%). The patient in whom no adenoma had been found was subsequently operated elsewhere where a single adenoma was retrieved (consistent with the preoperative MIBI). The other patient underwent a second operation which revealed a second (larger) adenoma.

The overall incidence of solitary adenoma was 96%, multiglandular disease 3% and carcinoma 1%. Postoperative complications included one permanent recurrent laryngeal nerve damage following a MIP (1%), two transient recurrent laryngeal nerve palsy’s (2%) and 2 postoperative haematomas (2%) both requiring surgical re-exploration.

The operative findings correlated with a preoperative MIBI suggesting a solitary adenoma in 72 of the 75 patients (PPV = 96%). In 16 of 21 patients who had a CT/US visualizing an assumed solitary adenoma, a single parathyroid abnormality was retrieved accordingly (PPV = 76%). When US and CT unequivocally identified one parathyroid abnormality (n = 16), the operative findings were consistent with these investigations in ten patients. In eleven out of 100 patients imaging did not correlate with the intraoperative findings (Table 2).

The sensitivity of preoperative imaging to correctly identify a solitary adenoma increased from 74% after MIBI alone to 92% following additional CT and US. At the same time, the overall PPV decreased from 96 to 90 percent respectively. The workup success rate of our strategy was 89% and the rate of successful MIP increased from 60 to 72%.

### 4. Discussion

In the present study the additional yield of ultrasound and CT after a negative scintigraphy was evaluated. Following a “negative” MIBI scintigraphy in one quarter of the patients, subsequent US and CT suggested a solitary adenoma in the majority of them. The proportion of patients with correctly identified solitary adenomas increased from 75% to 92%, and the proportion of patients...
who underwent successful minimally invasive parathyroidectomy from 60% to 72%.

The strength of the present study is its prospective design and the adherence to an algorithm using MIBI-sцинтigraphy, neck ultrasound and CT stepwise to identify solitary adenomas in patients with pHPT. All three imaging techniques are readily available techniques.

The main weakness is the limited number of patients, making firm conclusions difficult. Then again, it does reflect the ability to achieve a good surgical success rate in a modest volume setting even in MIBI “negative” patients. The observed surgical success rate in a modest volume institution contradicts the conclusions from others to treat MIBI “negative” patients only in high volume institutions [20]. Furthermore, we did not investigate the contemporary use of SPECT or SPECT/CT, however MIBI is a readily available technique and was used in our hospital in the past decade. Lastly, the proportion of patients with multiglandular disease was low in the present study, which is in line with our recent multi-institutional study observing a significantly lower incidence of multiglandular disease than previously reported [21].

Preoperative parathyroid adenoma localization is a prerequisite for a focused surgical approach in patients with pHPT and many imaging techniques and strategies are available and used for that purpose. MIBI-scans, ultrasonography, MRI, CT, SPECT are all used in the work-up of patients with pHPT with reported sensitivities ranging between 20% and 96%.

High cure rates in patients with primary hyperparathyroidism and two positive imaging studies are described [22,23]. Many authors have reported on MIBI-sцинтigraphy in combination with neck ultrasonography [24-28]. Ultrasonography has the advantage of being a readily available, cheap, preoperative localization study without the use of radiation, but it is strongly operator depended and the resulting image is difficult to interpret by the operating surgeon. CT has the benefit of providing the exact localization (even in an ectopic localization) of the enlarged gland thereby providing a roadmap for the operating surgeon. CT is showing unilateral uptake justifies this approach. The positive predictive value of 96% when a MIBI-scan is showing unilateral uptake justifies this approach. The contemporary use of SPECT or SPECT/CT may further increase this percentage in the near future, but it is accompanied by an increase in costs and patient radiation doses [18].

The increasing number of false positive imaging studies appears to be a disadvantage of the algorithm. The chance of a false positive investigation increases when the MIBI is negative, and even more when the subsequent US and CT show equivocal results. Awareness of this decreasing reliability of a positive imaging study is important and should be communicated with the patient. Nevertheless, our data demonstrate that there is little if no harm of an opportunistic minimally invasive exploration; it selects two-third of patients who had a “negative” MIBI who can profit from a MIP. One may argue that the conversion rate in this group was high, but these patients would have had an upfront CNE anyway if the CT/US had not been done in addition.

Pushing the limits by the stepwise use of readily available imaging techniques increases the identification rate of solitary adenomas in patients with pHPT and selects more patients for minimally invasive surgery.
