ABSTRACT

Acanthosis nigricans is characterized by papillomatous brownish lesions mainly in the intertriginous areas. We used dermoscopy to examine such lesions in a family with acanthosis nigricans. The dermoscopic images showed an aberrant skin structure of linear crista cutis and sulcus cutis, and hyperpigmented dots in crista cutis. The hyperpigmented dots, which could not be seen with the naked eyes, may contribute to the color of the pigmented skin. Dermoscopy can be useful for evaluating disorders involving the structure of area cutanea and a change in skin color.

Keywords: Dermoscopy; Acanthosis Nigricans; Hyperpigmented Dots; Crista Cutis; Sulcus Cutis

1. Introduction

Acanthosis nigricans (AN) can be present in the following forms: inherited, obesity-associated, autoimmune-related, drug-induced, and malignancy-associated. Inherited AN is a heterogeneous disorder, sub-classified into non-syndromic and syndromic forms [1]. AN is characterized by papillomatous brownish lesions mainly in the intertriginous areas, such as the axillae, neck, genital and submammary regions. The non-syndromic form is present at birth or develops during childhood. Wider regions, including almost the entire skin, may be affected in some hereditary cases.

2. Case Report

A 12-year-old Japanese woman visited us with asymptomatic aberrant skin color and structure. The abnormalities had been noticed during infancy. She had no other congenital malformations or delays in mental and physical development. The proband’s father and her 11-year-old brother had similar abnormal skin color and structure. A physical examination of the proband revealed asymptomatic and hyperpigmented papillomatous lesions over almost the entire body, especially in the intertriginous areas, such as the axillae and the neck (Figure 1(a)). The younger brother showed a similar clinical phenotype (Figure 1(b)). Dermoscopy of the proband’s neck showed linear crista cutis and sulcus cutis (Figure 1(c)). Focal hyperpigmented dots were present in the crista cutis. Dermoscopy of the brother’s neck revealed a similar aberrant skin structure with focal pigmented dots (Figure 1(d)). Unfortunately, we could not verify the origin of focal pigmented dots and precise structure of papillomatous projections with histopathological specimens, as the parents did not agree with biopsies.

3. Discussion

Dermoscopic images in two siblings with non-syndromic hereditary AN identified hyperpigmented dots that could not be seen with the naked eyes. The dermoscopic features of linear crista cutis would reflect the papillomatous projections of the dermis. We could not take biopsy specimens, even though histopathologic specimens are essential to confirm the origin of the hyperpigmented dots, i.e., increased melanin granules per melanocytes, an increased number of melanin contents-containing keratinocytes, or some other non-melanin-associated pigmentation.

Syndromic acanthosis nigricans is caused by specific activating mutations in FGFR2 and FGFR3 [1]. FGFR2b, the form expressed in the epidermis, mediates FGF signals to RAS-RAF-MAPK and phosphoinositol-3 kinase signaling cascades. Epidermal nevi represent mosaic forms of syndromic AN (FGFR3) and of neuro-cardio-facial-cutaneous syndromes (HRAS, NRAS, and KRAS), a
Dermoscopic Features of Hyperpigmented Dots in Crista Cutis in Two Siblings in a Japanese Family with Inherited Acanthosis Nigricans

Figure 1. (a) A clinical picture of a 12-year-old Japanese woman; (b) A clinical figure of her 11-year-old Japanese brother; (c) A dermoscopic image of the neck of the 12-year-old Japanese woman. It is characterized by miniature hyperpigmented dots and aberrant crista cutis and sulcus cutis. The dermoscopic image of the proband is more highly magnified; (d) A dermoscopic illustration of her 11-year-old Japanese brother. It showed similar hyperpigmented dots and aberrant crista cutis and sulcus cutis.

With dermoscopy in two siblings, we confirmed hyperpigmented dots and aberrant structure of crista cutis and sulcus cutis. Dermoscopy is useful for evaluating the disorders involving structure of crista cutis and sulcus cutis with a change of color as shown in a case of generalized Dowling-Degos disease [4] or in a variant of linear atrophoderma of Moulin [5].

We reported dermoscopic features in two siblings in a family with inherited non-syndromic AN. Further study with histopathologic correlations of dermoscopic findings in AN should be addressed to recognize more precise pathogenesis.
