ABSTRACT

Sol gel spin coating method has been successfully employed for the deposition of nanocrystalline nickel oxide (NiO) thin films. The films were annealed at 400°C - 700°C for 1 h in an air and changes in the structural, morphological, electrical and optical properties were studied. The structural properties of nickel oxide films were studied by means of X-ray diffraction (XRD) and scanning electron microscopy (SEM). XRD analysis shows that all the films are crystallized in the cubic phase and present a random orientation. Surface morphology of the nickel oxide film consists of nano-crystalline grains with uniform coverage of the substrate surface with randomly oriented morphology. The electrical conductivity showed the semiconducting nature with room temperature electrical conductivity increased from $10^{-4}$ to $10^{-2}$(Ωcm)$^{-1}$ after annealing. The decrease in the band gap energy from 3.86 to 3.47 eV was observed after annealing NiO films from 400°C - 700°C. These mean that the optical quality of NiO films is improved by annealing.

Keywords: Nickel Oxide, Sol Gel Method, Structural Properties, Optoelectronic Properties

1. Introduction

Metal oxides can adopt a large variety of structural geometries with an electronic structure that may exhibit metallic, semiconductor, or insulator characteristics, endowing them with diverse chemical and physical properties. Therefore, metal oxides are the most important functional materials used for chemical and biological sensing and transduction. Moreover, their unique and tunable physical properties have made themselves excellent candidates for electronic and optoelectronic applications. Nanostructured metal oxides have been actively studied due to both scientific interests and potential applications [1,2].

NiO is an important antiferromagnetic p-type semiconductor with excellent properties such as gas-sensing, catalytic and electrochemical properties, and has been studied widely for applications in solid-state sensors, electrochromic devices and heterogeneous catalysts as well as lithium batteries. The nickel oxide thin films have been prepared using various techniques including thermal evaporation [3], spray pyrolysis [4], chemical vapor deposition [5], electrochemical deposition [6], sol-gel [7,8], sputtering [9-11], chemical solution deposition [12-16], etc. Among these, chemical solution deposition, also called as a chemical bath deposition, is an advantageous technique due to its low cost, low-temperature operating condition and freedom to deposit materials on a variety of substances. Verkey and Fort [14] deposited nickel oxide thin films using nickel sulfate and ammonia solution over the temperature range 330 - 350 K. Pramanik and Bhattacharya [12] prepared nickel oxide thin films from an aqueous solution composed of nickel sulfate, potassium persulfate, and ammonia at room temperature. Han et al. [15] studied growth mechanism of nickel oxide thin films following Pramanik’s chemistry. Banerjee et al. [16] obtained hexagonal mesoporous nickel oxide using dodecyl sulfate as a surfactant and urea as a hydrolyzing agent.

To the best of our knowledge, few works are available in the literature on the sol-gel synthesis and characterization of NiO-based nanosystems [7,8].
In the present study, we report new method of synthesis and characterization of nanocrystalline NiO thin films by simple and inexpensive sol-gel spin coating technique and effect of annealing on their structure, morphology, electric transport and optical properties.

2. Experimental Details

Nanocrystalline NiO thin films have been synthesized by a sol-gel method using Nickel acetate Ni(CH$_3$COO)$_2$·4H$_2$O as a source of Ni. In a typical experiment; 3.322 gm of nickel acetate was added to 40 ml of methanol and stirred vigorously at 60°C for 1 hr, leading to the formation of light green colored powder. The as prepared powder was sintered at various temperatures ranging from 400 - 700°C with a fixed annealing time of 1hr in an ambient air to obtain NiO films with different crystallite sizes. The nanocrystalline NiO powder was further dissolved in m-cresol and solution was continuously stirred for 11 h at room temperature and filtered. The filtered solution was deposited on to a glass substrate by a single wafer spin processor (APEX Instruments, Kolkata, Model SCU 2007). After setting the substrate on the substrate holder of the spin coater, the coating solution (approximately 0.2 ml) was dropped and spin-cast at 3000 RPM for 40 s in an air and dried on a hot plate at 100°C for 10 min. Figure 1 shows the flow chart for the sol-gel synthesis of the NiO films prepared by using the spin-coating technique. The structural properties of the films were investigated by means of X-ray diffraction (XRD) (Philips PW-3710, Holland) using Cu Kα radiation (λ = 1.5406 Å). The surface morphology of the films was examined by scanning electron microscopy (SEM) (Model Japan), operated at 20 kV. The room temperature dc electrical conductivity measurements were performed using four probe techniques. The optical absorption spectra of the NiO thin films were measured using a double-beam spectrophotometer Shimadzu UV-140 over 200 - 1000 nm wavelength range. The thickness of the film was measured by using weight difference method and Dektak profilometer.

3. Results and Discussion

3.1. NiO Film Formation Mechanism and Thickness Measurement

The mechanism of NiO film formation by the sol-gel spin coating method can be enlightened as follows:

$$\text{Ni(OH)}_2 + \text{Carbonaceous compounds} \xrightarrow{\text{Air annealing}} \text{NiO + H}_2\text{O}$$

The NiO thin film formation can be expressed by the following reactions:

$$\text{Ni(CH}_3\text{COO)}_2 \cdot 4\text{H}_2\text{O} + 2\text{CH}_3\text{CH}_2\text{OH} \rightarrow \text{Ni(OH)}_2 + 2\text{CH}_3\text{COOCH}_3 + 4\text{H}_2\text{O}$$

Since to improve crystallinity and remove hydroxide phase, films were annealed for 1 hr pure NiO film is formed after air annealing by following mechanism:

3.2. Structural Analysis

Structural analysis of the NiO films annealed at 400°C - 700°C was carried out by using CuKα radiation source of wavelength (λ = 1.54056Å) and the diffraction patterns of films were recorded by varying diffraction angle (2θ) in the range 20 - 80°. Figure 2 shows XRD pattern for

Figure 2. X-ray diffraction patterns of NiO film at different annealing temperatures.

Figure 3(a-d). The two-dimensional high magnification surface morphologies of NiO thin films annealed at 400 °C - 700 °C were carried out using SEM images are shown in Figure 3(a-d). From the micrographs, it is seen that the film consists of nanocrystalline grains with uniform coverage of the substrate surface with randomly oriented morphology and the crystallite size is increased from 40 - 52 nm as annealing temperature increases from 400 °C - 700 °C. The crystallite size calculated from SEM analysis is quite in good agreement with that of crystallite size calculated from XRD analysis. Similar results are also observed by Patil et al. [22] for sol gel derived TiO$_2$ films.

3.4. Electrical Transport Properties

3.4.1. Electrical Conductivity Measurement

The four-probe technique of dark electrical conductivity measurement was used to study the variation of electrical conductivity of film with annealing temperature. The variation of log $\sigma$ with reciprocal temperature (1000/T) is depicted in Figure 4. After annealing, room temperature electrical conductivity was increased from $10^{-4}$ to $10^{-2}$ (Ω·cm)$^{-1}$, due to increase in the crystallite size and reduced scattering at the grain boundary. Similar type of increase in electrical conductivity has been observed by Patil et al. [22]. From Figure 4 it is observed that the conductivity of film is increases with increase in annealing temperature, further it is observed that conductivity obeys Arrhenius behavior indicating a semiconducting transport behavior. The activation energies were calculated using the relation:

$$\sigma = \sigma_0 \exp\left(-\frac{E_a}{kT}\right)$$  \hspace{1cm} (3)

where, $\sigma$ is the conductivity at temperature $T$, $\sigma_0$ is a constant, $k$ is the Boltzmann constant, $T$ is the absolute temperature and $E_a$ is the activation energy. The activation energy represents the location of trap levels below the conduction band. From Figure 4, activation energy (HT) was increases from 0.110 eV, to 0.481 eV, when film annealed from 400 °C - 700 °C indicating no significant change.

3.4.2. Thermo-emf Measurement

The dependence of thermo-emf on temperature is de-

The optical absorption spectra in the range of 200 - 1000 nm for NiO thin films annealed at 400 - 700°C were carried out at room temperature without taking in account of scattering and reflection. Figure 6 shows the optical absorption spectra of NiO thin films annealed at 400°C - 700°C, it is observed that the absorption coefficient is very low for photon energy in the IR and visible region while the sudden increase in the absorption coefficient

Figure 7. Plot of (αhν)² versus (hv) of NiO thin film for different annealing temperatures.

occurs in the near UV region. It was found that, the absorption coefficient of films is increases with increase in annealing temperature. This could be because of increase in the density of states of holes with increase in annealing temperature, similar results are reported by Varkey et al. [24] and Pejova [25]. The optical band gap (E_g) of NiO thin films annealed at 400°C - 700°C is calculated on the basis of optical absorption spectra using the following equation:

\[ \alpha = \frac{A(E_g - h\nu)^n}{h\nu} \]  

where ‘A’ is a constant, ‘E_g’ is the semiconductor band gap and ‘n’ is a number equal to 1/2 for direct gap and 2 for indirect gap compound.

The plots of (αhν)² versus hv of films annealed at 400°C - 700°C are shown in Figure 7.

Since the plots are almost linear, the direct nature of the optical transition in β-Ni(OH)₂ and NiO is confirmed. Extrapolation of these curves to photon energy axis reveals the band gaps. The band gap was found to be decreased from 3.86 to 3.47 eV for films annealed at 400°C - 700°C. Varkey and Fort [14] reported the slightly lower band gaps 3.75 and 3.25 eV for as-prepared NiOOH and annealed NiO thin films [24]. The decrease in E_g with annealing temperature could be due to increase in crystalline size and reduction of defect sites. This is in good agreement with the experimental results of XRD analysis. According to XRD results, the mean grain size has increased with increased annealing temperature. As the grain size has increased, the grain boundary density of a film decreased, subsequently, the scattering of carriers at grain boundaries has decreased [25]. A continuous increase of optical constants and also the shift in absorption edge to a higher wavelength with increasing annealing temperature may be attributed to increase in the particle size of the crystallites along with reduction in porosity.

The decrease in optical band gap energy is generally observed in the annealed direct-transition-type semiconductor films. Hong et al. [26] observed a shift in optical band gap of ZnO thin films from 3.31 - 3.26 eV after annealing, and attributed this shift to the increase of the ZnO grain size. Chaparro et al. [27] ascribed this ‘red shift’ in the energy gap, E_g, to an increase in crystallite size for the annealed ZnSe films. Bao and Yao [28] also
reported a decrease in $E_g$ with increasing annealing temperature for SrTiO$_3$ thin films, and suggested that a shift of the energy gap was mainly due to both the quantum-size effect and the existence of an amorphous phase in thin films. In present case, the mean crystallite size increases from 40 to 70 nm after annealing from 400°C - 700°C. Moreover, it is understood that the amorphous phase is reduced with increasing annealing temperature, since more energy is supplied for crystallite growth, thus resulting in an improvement in crystallinity of NiO films. Therefore, it is believed that both the increase in crystallite size and the reduction in amorphous phase cause are decreasing in band gap of annealed NiO films. The change in optical band gap energy, $E_g$, reveals the impact of annealing on optical properties of the NiO films.

4. Conclusions

Nanocrystalline nickel oxide thin films were prepared by low-cost sol gel spin coating technique. The NiO films were annealed for various temperatures between 400 to 700°C. The XRD results revealed that the NiO thin film has a good nanocrystalline cubic structure. The SEM results depict that a uniform surface morphology and the nanoparticles are fine with an average grain size of about 40 - 60 nm. The dc electrical conductivity is increased from $10^{-4}$ to $10^{-2}$ (Ω cm)$^{-1}$ for films annealed at 400°C - 700°C. Optical absorption studies show low-absorbance in IR and visible region with band gap 3.86 eV (at 400°C) which was decreased to 3.47 eV (at 700°C). This has been attributed to the decrease in defect levels. The $p$-type electrical conductivity is confirmed from thermoelectric measurement with no appreciable change in thermoelectric power after annealing
