ABSTRACT

We investigate the effect of synthesized time on the structure, as well as optical properties in ZnWO₄ nanorod prepared by hydrothermal method. The prepared rods were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), Raman scattering, absorption and photoluminescent (PL) spectra techniques. The size and morphology of ZnWO₄ nanorod can be controlled by adjusting the reaction time. The resultant sample is a pure phase of ZnWO₄ without any impurities. The results showed that the optical property of ZnWO₄ nanoparticles obviously relied on their rod sizes.

Keywords: ZnWO₄ Nano Rod, Raman Spectroscopy, Absorption, Photoluminescence

1. Introduction

Zinc tungstate (ZnWO₄) with a wolframite structure has been of practical interest for a long time because of its attractive luminescence [1]. ZnWO₄ has been applied as a possible new material for microwave amplification by stimulated emission of radiation [2], scintillator [3] and optical hole burning lattice material [4], etc. Recently, new applications for this material have emerged, including large-volume scintillators for high-energy physics [5]. In particular, ZnWO₄, also known by its mineral name sammartinite, is a wide-gap semiconductor, with band gap energy close to 4 eV [6], and is a promising material for the new generation of radiation detectors.

ZnWO₄ has been prepared by different routes such as the Czochralski method [7], sintering of WO₃ and ZnO or ZnCO₃ powders [8], reaction in aqueous solution followed by heating of the precipitate [9], heating of ZnO thin films with WO₃ vapor [10], sol-gel reaction [11], and hydrothermal reaction over an extensive period [12]. However, ZnWO₄ particles prepared by these routes are relatively large in particle size and irregular in morphology. Furthermore, higher calcining temperature is still needed. It is very significant whether in fundamental or applied field to explore new routes to ZnWO₄, especially for ZnWO₄ crystallites with nanometer size, which would have unique properties compared to traditional products [13,14]. To obtain nanosized powders, the solid state methods have several problems, because the WO₃ has a tendency to vaporize at high temperatures [15], nonhomogeneous compounds might be easily formed during the solid-state and melting processing and the temperature for the solid state reaction is relatively high [16]. These problems could be solved by applying the hydrothermal method. However, a few studies on the chemical synthesis of zinc tungstate by the hydrothermal method have been reported. Furthermore, very few papers were concerned with effects of the size and morphology on the optical properties of ZnWO₄ nanoparticles.

In this work, we report the synthesis of ZnWO₄ nanorod by hydrothermal method at a low temperature of 180°C and investigate their structure, Raman scattering, absorption and photoluminescence.

2. Experiment

Zinc tungstate (ZnWO₄) nanoparticles were prepared by the hydrothermal reaction of Zn(NO₃)₂·6H₂O and Na₂WO₄·2H₂O at temperature of 180°C, and various reaction times (2, 4, 6 and 8 h). In a typical procedure for the preparation of sample, Zn(NO₃)₂·6H₂O (1 mmol) in water (10 ml) was added Na₂WO₄·2H₂O (1 mmol) in water (20 ml) with vigorous stirring. H₂O was added to make 40 ml of the solution, and pH of the solution was maintained at 7.
adjusted to 6.68, respectively, with dilute of 30% NH$_3$·H$_2$O solution. The solution was then added into a Teflon-lined stainless steel autoclave of 100 ml capacity. The autoclave was heated to 180°C for 2, 4, 6 and 8 h, respectively, without shaking or stirring. Afterwards, the autoclave was allowed to cool to room temperature gradually. The white precipitate collected was washed with distilled water four times. The solid was then heated at 80°C and dried under vacuum for 2.5 h.

Structural characterization was performed by means of X-ray diffraction using a D5005 diffractometer with Cu Kα radiation. The FE-SEM observation was carried out by using a S4800 (Hitachi) microscope. Raman measurements were performed in a back scattering geometry using Jobin Yvon T 64000 triple spectrometer equipped with a cryogenic charge-coupled device (CCD) array detector, and the 514.5 nm line of Ar ion laser. The absorption spectra were recorded by using Jasco 670 UV-vis spectrometer and the room temperature luminescent spectra were recorded on a spectrofluorometer (PL, FluoroLog-3, Jobin Yvon Inc, USA).

3. Result and Discussion

3.1. Structure

Figure 1 shows the XRD patterns of ZnWO$_4$ powders heated for 2, 4, 6 and 8 h as a function of the reaction time. It is noted that the ZnWO$_4$ single phase could be observed in all XRD patterns. All diffraction peaks of ZnWO$_4$ crystal appeared when the sample was prepared at 180°C, which could be easily indexed as a pure, monoclinic wolframite tungstate structure according to the standard card (JCPDS Card number: 73-0554). It was found that, the optimum temperature for the production of the high-quality crystal was as high as 180°C [17].

The morphologies and microstructures of the samples were then investigated with SEM. Figure 2 shows that the morphologies and dimensions of the samples were strongly dependent on the reaction time. SEM micrograph for the sample synthesized for 2 h was basically irregular (Figure 2a). With the increase of the reaction time to 4 h, the rod-shaped crystals can be seen (Figure 2b), and the rod size was in the range from several nanometers to several tens of nanometers. For 6 h, the crystal was basically rod-like (Figure 2c). When the reaction time was raised to 8 h, the rod-shaped crystals grew larger and longer and a majority of the crystals have exceeded 50 nm in length, the sizes of the rods became homogeneous (Figure 2d). However, it was shown that, for longer reactive times, such as 48 h, the crystal phase instead became inhomogeneous, which could be due to the breakage of the large crystal under such conditions, suggesting the worse crystallinity [12]. The inset of Figure 1 shows the average crystallite sizes for the heat-treated powders calculated by XRD line broadening method [18]. The calculated average crystallite sizes were 22.02, 25.00, 26.05 and 26.00 nm for the heat-treated powders at 2, 4, 6 and 8 h, respectively. These are corresponding to the SEM observation in Figure 2 showing an ordinary tendency to increase with the reaction time from 2 h to 8 h. However, Zhao et al. [19] has investigated the calcinations time and concluded that the calcination time plays little effect on the crystal phase of ZnWO$_4$. This comment was contrary to our result.

3.2. Absorption Spectroscopy

Figure 3 shows a diffuse reflection spectrum of ZnWO$_4$ nanopowder. Steep shape of the spectra indicated that the UV light absorption was due to the band-gap transition instead of the transition from the impurity level. For a

Crystalline semiconductor, the optical absorption near the band edge follows the equation: \( a h \nu = A(h \nu - E_g)^{1/n} \), where \( a \), \( h \), \( E_g \) and \( A \) are absorption coefficient, light frequency, band gap, and a constant, respectively [20]. For the ZnWO₄, \( n \) is determined to be 2. Thus, the band gaps of the ZnWO₄ nanopowders were roughly estimated to be 3.78, 3.76, 3.73 and 3.72 eV, as shown in the inset of Figure 3. Bonanni et al. [21] reported that the band gap of ZnWO₄ was 3.75 eV, which is in agreement to our experimental values. However, the band gap becomes narrower in the sample with longer reaction time. Therefore, the crystallization degree may contribute to the absorption edge shift.

3.3. Raman Spectroscopy

Figure 4 illustrates the Raman spectra for ZnWO₄ nanopowders. It is clear that, the peaks shifts to higher frequency as increasing the reaction time. Studies of the optical properties and the Raman spectra of ZnWO₄ at room temperature have been reported in the literature [22]. ZnWO₄ has the monoclinic wolframite structure with \( C_{2h} \) point group symmetry and \( P2/c \) space group. It has two formula units per unit cell. The W-O interatomic distance is substantially smaller than that of Zn-O, therefore, to a first order approximation, the lattices can be separated into internal vibrations of the octahedra and the external vibrations in which an octahedron vibrates as a unit. A group theoretical calculation of the ZnWO₄ structure yields 36 lattices modes, of which 18 are Raman active (\( 8A_g + 10B_g \)).

It is assigned to the \( A_g \) mode observed near 907 cm\(^{-1}\) since, as is the case of the regular octahedron, the symmetric stretch is expected to have the highest frequency of all the internal modes. The \( E_g \) mode (asymmetric stretch) of the regular octahedron splits into \( A_g + B_g \) by the crystal field. Again, these modes are expected to have frequencies that are higher than those of the bending mode (\( T_{2g} \)) of the regular octahedron. The obvious choices are the \( B_g \) and \( A_g \) modes observed near 786 and 709 cm\(^{-1}\), respectively. The remaining modes \( 2A_g + B_g \) with frequencies of 407, 342 and 190 cm\(^{-1}\) are assigned to the \( T_{2g} \) mode of the regular octahedron.

In a first attempt to identify the six internal stretching modes of the W-O atoms in the distorted WO\(_6\) octahedra of ZnWO₄, Liu et al. [23] assigned them to the modes at 906, 787 and 407 cm\(^{-1}\) on the basis of bond lengths and Raman frequencies in the WO\(_6\) group. Afterwards, Wang et al. [24] assigned the internal stretching modes to the phonons observed near 906, 787, 709, 407, 342, and 190 cm\(^{-1}\) on the basis of the temperature dependence of the Raman frequencies. However, this assignment is in contradiction with the fact that the frequencies of the internal modes are expected to be higher than those of the external modes. These authors argue in favor of their assignment that the oxygen sharing between WO\(_6\) and ZnO\(_6\) octahedra may cause a considerable overlap in the frequency range for the two types of vibrations.

3.4. Photoluminescence

Figure 5 shows the representative PL spectra of the ZnWO₄ crystallites synthesized by the hydrothermal method for 2, 4, 6 and 8 h. With the exited wavelength at 320 nm, the corresponding emission peaks centered at ~500 nm can be observed. Obviously, the ZnWO₄ nanorods, prepared at the same calcining temperature (180°C) with a shorter holding time, exhibit lower emission intensity than that from longer time. It implies PL properties of the ZnWO₄ nano-rods are strongly affected by their long scale. This broad emission band had a shoulder in the blue region, indicating it consisted of more than one emission band. The PL spectra were fit to three peaks using a Gauss function as shown in Figure 6.

The PL spectrum for the ZnWO₄ film also consisted of an emission band at 2.50 eV (495 nm) and two emission...
bands at 2.80 eV (448 nm) and 2.28 eV (545 nm). To clarify, we show only the fitting figure of the sample with reaction time for 8 h.

It is well established that the $W_6^{6-}$ complex and a slight deviation from perfect order in the crystal structure are responsible for the emission bands [25]. But there exist different opinions concerning the origin of these bands. Lammers [26] and Grigorjeva [27] believed that the blue and green emissions originated from the intrinsic $W_6^{6-}$ complex with a double emission from one and the same center ($^3T_{1u} \rightarrow ^1A_{1g}$), whereas the yellow emission is due to recombination of e-h pairs localized at oxygen atom deficient tungstate ions. However, Ovechkin [28] ascribed the blue band to the self-trapped exciton in tungstenite crystals with strong electron–phonon coupling, and the green and yellow bands to the transitions of $T_{2g} \rightarrow T_{2g}$ and $T_{1g} \rightarrow T_{2g}$ in the $W_6^{6-}$ complex. Almost all investigations in luminescent properties of ZnWO$_4$ have been carried out for large crystals and films. The nanosized ZnWO$_4$ prepared via a hydrothermal route in the current work showed luminescent properties similar to those of bulk ZnWO$_4$. The luminescence intensities varied from sample synthesized for 2 h to sample synthesized for 8 h. Nanorods with a longer synthesized time exhibited a strong luminescence, and nanorods with a shorter synthesized time gave weak luminescence. These results suggest that morphologies and sizes of nanoparticles may affect their luminescence characteristics. Further studies on PL property of the as-prepared ZnWO$_4$ crystallites are in progress.

## 4. Conclusions

In conclusion, ZnWO$_4$ nano-particles were successfully synthesized at 180°C by a hydrothermal route. The morphology and dimension of the ZnWO$_4$ crystallites were affected by synthesized time. The optical band gap becomes narrower as increasing the reaction time. The improved PL properties of the ZnWO$_4$ crystallites can be obtained with the increase of the rod scale. Because the crystallite size of ZnWO$_4$ for the nano rod is far large, therefore, the absorption edge shift cannot result from quantum size effect but prolonged rod.
