Abstract

This study deals with the grinding of mill scale in a laboratory ball mill for different milling time then briquetted by using 2% molasses as a binder and investigates the effect of grinding of mill scale for different time on the physicochemical properties and the reduction degree of the mill scale briquettes via hydrogen. Diffusion process control equation was applied and the energy of activation was calculated = 28.33 kJ/mole.

Keywords

Grinding Time, Mill Scale, Reduction via H₂

Subject Areas: Inorganic Chemistry, Material Experiment

1. Introduction

In integrated steelmaking processes, some dusts, sludges, mill scale etc., commonly called residual materials, are inevitably generated along with the production of steel. The steelmaking by-products very rich in iron (≈72% Fe) are currently produced in large quantities and represent a potential of almost 5 million tons in the world [1] [2]. Dumping of residual materials is not allowed by environmental protection regulations [3]. Generally, these by-products are recycled by the metallurgical processes such as the blast furnace or the direct reduction reactors that use coal as the reducing agent to produce pre-reduced pellets intended for remelt in electric steel plants. Besides the steelmaking, recycling part of these by-products is already supported by the powder metallurgy where the economic recovery is more favorable [1] [2].

http://dx.doi.org/10.4236/oalib.1101016
Mill scale is a steelmaking by-product from the rolling mill in the steel hot rolling process. Mill scale contains both iron in elemental form and three types of iron oxides: Wustite (FeO), Hematite ($\alpha$-Fe$_2$O$_3$) and Magnetite (Fe$_3$O$_4$). The chemical composition of mill scale varies according to the type of steel produced and the process used. The iron content is normally around 70%, with traces of non-ferrous metals and alkaline compounds. The reduction of rolling mill scale to sponge iron powder is a new way to take advantage of a cheap by-product of the steelmaking industry, yielding sponge iron that can be re-used to the electric furnace as metallic charge for steelmaking to obtain a product with a lower residual content and improved properties [3]-[5].

Mechanical activation pretreatment of minerals by intensive milling can improve the efficiency of subsequent processes such as leaching, reduction, chemical synthesis, etc. Consequential benefits of mechanical activation, besides higher efficiencies may include lower reaction temperatures and enhanced kinetics. As a result, the subsequent processing can be performed in simpler and less expensive reactors with shorter reaction time [6]-[8]. Several factors, most importantly the formation of new and additional surface area as well as creation of lattice defects, are responsible for the mentioned improvements [6] [9]-[14]. Different types of milling apparatus such as ball mills, planetary mills, vibratory mills, pin mills and rolling mills may be used for milling operations [15].

Mechanical treatment in a high energy mill generates a stress field within solids. Stress relaxation can occur via several channels: 1) heat release; 2) development of surface area as a result of brittle fracture of the particles; 3) generation of various sorts of structural defects and 4) stimulation of chemical reaction within solids. All relaxation channels cause changes in the reactivity of the solid substance under treatment, which is why the resulting action is called mechanical activation [16]. The concentration of the mechanically induced defects and their spatial distribution depend upon the condition of the energy transfer in the mill. The concentration and distribution of the mechanically induced defects can be also influenced by varying the external conditions of stress. The creation of defects enhances the stored energy (enthalpy) in the solids and consequently causes a decrease of activation barrier for the process and/or subsequent processes [17]. A large number of studies have been devoted to the understanding of the influence of the grinding variables and conditions on the structural changes of mechanically-activated material. Structural changes of inorganic oxides have been shown to be intensified with increasing grinding media density, acceleration and duration of milling in a planetary mill [18]. It has been further reported that the crystallite size decreased exponentially with increasing milling time and the strain increased by extending activation time during mechanical activation of ilmenite [19]. A comparative study of the influence of attritor and ball vibratory mills on the reactivity of sulphide minerals was carried out by Balaz et al. [20]. $\gamma$-Fe$_2$O$_3$ samples ground with smaller amplitude in a vibratory mill showed higher reactivity [21].

The aim of this work is to investigate the effect of grinding duration on the physical quality and the kinetic reduction behavior of mill scale briquettes by hydrogen.

2. Experimental Procedures

2.1. Characterization of Mill Scale

2.1.1. Sieve Analyses
Mill scale used in this experiment delivered from Iron and Steel Co. This mill scale was grind in laboratory ball mill for different hours from 1 hour up to 4 hours. This mill scale before and after grinding was subjected to sieve analysis by Tyler standard sieve set with electric shaker and the results is illustrated in Figure 1 and the mean size of mill scale is present in Table 1.

2.1.2. Chemical Analyses
The chemical analysis of mill scale shows that it contains Fe total 69.33 weight% in the form (Fe$_2$O$_3$ 70 weight %, Fe$_3$O$_4$ 17.26 weight% and FeO 7.83 weight %). Sulphur 0.33 weight%, Phosphorus 0.22 weight%, MnO 0.66 weight%, SiO$_2$ 1.92 weight% and carbon 0.04 weight%.

2.1.3. X-Ray Analysis
While the X-ray analysis of mill scale is illustrated in Figure 2, as it is clear from this figure that mill scale mainly consists of magnetite, wustite, iron, quartz and hematite.

2.2. Preparation of the Briquettes and Its Physical Properties
The fine mill scale particles (10 g) after grinding for different time in laboratory ball mill are mixed with 2%

molasses and then pressed in the mould (12 mm diameter and a height 22 mm using MEGA KSC-10 hydraulic press. Under different pressure (the pressure ranges from 75 MPa up to 250 MPa). The produced briquettes were subjected to drop damage resistance tests and compressive strength tests. The drop damage resistance indicates how often green briquettes can be dropped from a height 46 cm before they show perceptible cracks or crumble. Ten green briquettes are individually dropped on to a steel plate. The number of drops is determined for each briquette. The arithmetical average values of the crumbling behavior of the ten briquettes yield the drop damage resistance for these briquettes, while the average compressive strength is done by compressed 10 briquettes between parallel steel plates up to their breaking [22].

2.3. Reduction Procedures

The reduction of mill scale briquette with hydrogen was performed in thermogravimetric apparatus. This scheme is similar to that present elsewhere [23] (Figure 3). It consisted of a vertical furnace, electronic balance for
monitoring the weight change of reacting sample and temperature controller. The sample was placed in a nickel chrome crucible which was suspended under the electronic balance by Ni-Cr wire. The furnace temperature was raised to the required temperature (650°C - 950°C) and maintained constant to ±5°C. Then samples were placed in hot zone.

The nitrogen flow rate was 0.5 l/min pass through furnace in all the experiments at initial time air should be removed before each experiment and also after the end of reduction. The weight of the sample was continuously recorded at the end of the run; the samples were withdrawn from the furnace and put in the desiccators.

The percentage of reduction was calculated according to the following Equation (1):

$$\text{Percent of reduction} = \left[\frac{(W_o - W_t) \times 100}{\text{Oxygen mass}}\right]$$

where:

- \(W_o\): the initial mass of mill scale sample after removal of moisture;
- \(W_t\): mass of sample after each time, \(t\);
- Oxygen mass: indicates the mass of oxygen percent in mill scale in form FeO & Fe_2O_3.

### 3. Results and Discussions

#### 3.1. Effect of the Pressing Load with Constant Amount of Molasses on the Quality of the Wet and Dry Mill Scale Briquettes

Figures 4-7 show the relation between the change of pressing load at constant amount of molasses (2%) on the drop damage resistance and compressive strength of the wet and dry briquette. It is evident that as the pressing pressure load increased both the drop damage resistance and compressive strength increased. This may be due to the fact that increase pressure load increase the compaction of briquette and subsequently the Vander Waals forces increased [24] [25], also this may be due to the increase of briquetting pressure leads to progressive crushing of the macropores [26]. Also from these figures, it is clear that as the size of mill scale decrease (increase of time of grinding) both drop damage resistance and compressive strength of wet and dry briquette increased.

#### 3.2. Effect of the Grinding Time on the Reduction Percentage

Figure 8 illustrates the effect of change milling time on the degree of reduction of mill scale briquette at 900°C (pressing load 260.129667 MPa) for different time and at 1 l/min hydrogen flow rate. From this figure it is clear that the extent of the reduction increased as the milling time increased from 1 hr. up to 4 hr, this may be attributed to additional surface area as well as creation of lattice defects by the action of change milling time [6] [9]-[14].
3.3. Effect of Hydrogen Flow Rate on the Reduction Percentage

Figure 9 illustrates the relation between the reduction percentage and hydrogen flow rate when the reduction was done at constant temperature (900°C) and constant weight of the sample. It is clear that as the flow rate of hydrogen increased the reduction percentage increased. This may be the increase of flow rate leads to an in-
crease of number of hydrogen mole in the bulk phase, which in turn leads to the raise of hydrogen adsorption and subsequently the rate of reaction increased [27] or the increase of flow rate increased the gas diffusion across the boundary layer subsequently the reduced ion increased [28]. Also may be the higher flow rate prevailing in the reaction zone which enhances the rate of hydrogen absorption and subsequently the rate of chemical reaction steps increased [29]. But from the economic view, it is preferred to use 1.5 l/min. hydrogen flow rate in the rest of this investigation.
3.4. Effect of Varying Reduction Temperature on the Reduction Percentage

The reduction was carried out at different temperatures ranging from 600°C up to 950°C, where the weight of the briquette were constant and the hydrogen flow rate = 1.5 liter/min. The results of the investigation are shown in Figure 10 for the briquette binding by 2% molasses. It is clear that the increase of temperature favors the reduction rate and degree. The analyses of the curve relating the reduction percentage and time of reduction, shows that each curve has 3 different values of reduction rates. The first value is high, while the second is somewhat slower and the third is slowest one. The increase of reduction percentage with rise of temperature may be due to the increase of number of reacting moles having excess of energy which leads to the increase of reduction rate [27] [30]. Also the raise of temperature leads to an increase of the rate of mass transfer of the diffusion and rate of desorption [28] [31].

3.5. Kinetics of the Reduction Process

Kinetic studies for estimation of apparent activation energies were carried out for mill scale briquettes at different temperatures from 600°C up to 950°C for different time intervals in the range of 0 - 65 minutes.

1) By using diffusion process control equation (Jander and Anorg Equation (2)) [32]

\[
\left(1 - (1 - R)^{(1/3)}\right)^2 = kt
\]

where \(R\) is fractional reduction, \(t\) is time of reduction, \(k\) is the rate constant.

Figure 11 illustrates the relation between \(1 - (1 - R)^{(1/3)}\) against time of reduction for different reduc-
tion temperature. From which it is clear that the relationship is represented by straight line.

The natural logarithms were used according to the Arrhenius equation to calculate the activation energies of reduction reaction by using the calculated rate constant $k$.

$$k = k_0 \exp\left(-\frac{E}{RT}\right)$$

(3)

$$\ln k = \ln k_0 - \frac{E}{RT}$$

(4)

where $k_0$ is the coefficient; $E$ is the apparent reduction activation energy; $R$ is the universal gas constant $[8.314 \times 10^{-3} \text{kJ/(mol}\cdot\text{K})]$; $T$ is the absolute temperature. The relationships between the natural logarithm of reduction rate constant and the reciprocal of absolute temperature for mill scale briquettes are shown in Figure 12, from which it is clear that briquette has activation 28.33 kJ/mole.

### 3.6. X-Ray Analyses of the Reduced Briquette

Figure 13 and Figure 14 show the X-ray analyses of the reduced mill scale briquette at 600˚C and 950˚C respectively. From which it is clear that the main phases in the reduced briquette are Iron Syn-Fe, Hematite and Magnetite. But Iron oxide (FeO) phase is present at 950˚C rather than in case at 600˚C.
Figure 14. X-ray analysis of mill scale briquette reduced at 950°C.

4. Conclusions

The reduction of mill scale grinding for different time ranging between 1 hr up to 4 hr. in the form of briquette (pressing load about 260 MPa) by hydrogen at varying temperatures from 600°C up to 950°C for different time and at 1.5 l/min hydrogen flow rate indicated that:

1) The reduction rates increased with increasing temperature of the reduction up to 950°C.

2) Diffusion process control equation (Jander equation) \( \left( \frac{1}{1-R} \right)^{1/3} = kt \) was applied and the energy of activation was calculated = 28.33 kJ/mole.
