Abstract

ZnSe quantum dot (QD) semiconductor optical amplifier (SOA) is studied theoretically using net gain for linear Absorption coefficient and linear emission and these results are used to calculate noise figure and small-signal gain.

Keywords: Linear Absorption Coefficient, Linear Emission Coefficient, Rate Equations (Res), Noise Figure

1. Introduction

Quantum dot photonic materials have attracted much attention in recent years as they have the potential to deliver the stability and coherence of atomic sources within a compact and efficient semiconductor device. Characteristics such as reduced sensitivity to optical feedback makes such materials attractive as laser sources. In addition, suppression of pattern effects in QD semiconductor optical amplifiers (SOAs) shown to be promises for high speed application. The understanding of the high speed carrier dynamics of these materials is crucial for their optimization and exploitation. To address this issue, time resolved spectroscopy has been used to investigate the fundamental carrier decay time scales of SOA structures and determine their suitability for high-speed applications. Such pump-probe studies are usually performed using pulse width of a few hundred femtoseconds to picoseconds in order to sufficiently resolve the relaxation dynamics of high-speed devices. [1] Quantum dot (QD) semiconductor optical amplifiers (SOAs) demonstrate best features when compared with other SOAs based on bulk or quantum well materials. As a result, QD SOAs are very promising for applications in high-speed optical communications. One of the most important features of QD materials results in these best performances is the discrete structure of their energy levels [2].

In this work, ZnSe/ZnS QD-SOAs are studied. First, energy levels are calculated using quantum box model where the dot is assumed in the form a cube with quantum dot size is $10 \times 10 \times 10$ nm$^3$, net gain is then calculated by using linear Absorption coefficient and linear emission coefficient components in the QD.

2. Gain of QDs

Gain and threshold current models are calculated with quasi-Fermi levels energies $E_{fc}$ and $E_{fv}$, which are directly controlled by the doping concentration or injected current. Given that $w_x$, $w_y$, and $w_z$ are the lengths in each dimension of a quantum box, see Figure 1, and $E_{c}$ and $E_{v}$ are allowed quantized electron and hole energies, respectively, the corresponding carrier densities, $n$ and $p$, may be expressed as

$$n = \sum_{m,l} 2 f_c \left( \frac{E_{c,m,l}}{E_{c}} \right) = \sum_{m,l} \frac{2}{1 + \exp \left( \frac{E_{c,m,l} - E_{c}}{kT} \right)} w_x w_y w_z \quad (1)$$

$$p = \sum_{m,l} 2 f_v \left( \frac{E_{v,m,l}}{E_{v}} \right) = \sum_{m,l} \frac{2}{1 + \exp \left( \frac{E_{v,m,l} - E_{v}}{kT} \right)} w_x w_y w_z \quad (2)$$

Figure 1. Diagram of dot/barrier quantum box.
Where \( f_e \) and \( f_h \) are the corresponding Fermi functions for electrons in the conduction and valence bands. The factor of two takes into account the electron spin. The summation is over all the confined energy states, which depends on the QD material and the dot/barrier valence and conduction band offsets \( \Delta E_c \) and \( \Delta E_v \) that enable electron and hole confinement. Solving known \( E_c \) and \( E_v \) are ed for directly and applied to find the linear absorption coefficient \( a(\omega) \) and linear emission coefficient \( e(\omega) \) components in the QD [3]

\[
a(\omega) = \frac{w}{n_e \sqrt{E_{\text{cont}} - E_c}} \sum_{E_c} g_{ce} f_c(E_c) [1 - f_E(E_c)] \left( \frac{\hbar}{\tau_{in}} \right) \left( E_c - \Phi \right) J dE_c \tag{3}
\]

\[
e(\omega) = \frac{w}{n_e \sqrt{E_{\text{cont}} - E_v}} \sum_{E_v} g_{ve} f_v(E_v) [1 - f_E(E_v)] \left( \frac{\hbar}{\tau_{in}} \right) \left( E_v - \Phi \right) J dE_v \tag{4}
\]

Where \( R_{cv} \) is the dipole moment, \( n_e \) is the refractive index and \( g_{cv} \) is the density of states for the QD, given by [3]

\[
g_{cv} = 2\delta \left( E_v - E_{\text{cont}} - E_c \right) \tag{5}
\]

Where \( \tau_{in} \) is the intraband relaxation time. Equations (3) and (4) signify the rates of absorption and emission per unit length with \( E_1 \) and \( E_2 \) representing the hole energy level in the valence band and the electron energy level in the conduction band, respectively. The net gain of the system is then [3]

\[
G(\omega) = e(\omega) - a(\omega) \tag{6}
\]

To determine the optimal operating region for an amplifier system, the gain coefficient, expressed as [3]

\[
gain \ coefficient = \frac{G(\omega)}{P_{in}} \tag{7}
\]

3. QD-SOA

Based on the rate equations used in [4] for the wetting layer (WL) carrier density \( N_{\text{w}} \), occupation probabilities for ground and exited states \( (f \ and \ h) \), respectively one can write.

\[
\frac{\partial N_w}{\partial t} = \frac{J}{qL_w} N_w (1 - h) + \frac{N_e h}{\tau_{e1}} - \frac{N_w}{\tau_{w1}} \tag{8}
\]

\[
\frac{\partial h}{\partial t} = \frac{N_e L_w (1 - h)}{N_w \tau_{e1}} - \frac{N_e h}{\tau_{e1}} \tag{9}
\]

\[
\frac{\partial f}{\partial t} = \frac{(1 - f)h}{\tau_{11}} - \frac{f}{\tau_{12}} - \frac{g_L}{N_0^2 (2f - 1) S_{av}} \frac{c}{\sqrt{e}} \tag{10}
\]

Where \( J \) is the current density, \( q \) is the electron charge, \( L_w \) is the effective thickness of the active layer, \( \tau_{e1} \) is the carrier relaxation time from the two-dimensional WL to the ES, \( \tau_{e2} \) is the carrier escape time from the ES to the WL, \( \tau_{w1} \) is the spontaneous radiative lifetime in WL, \( \tau_{wR} \) is the spontaneous radiative lifetime in the QDs, \( \tau_{21} \) is the carrier relaxation time from ES to GS, \( \tau_{12} \) is the carrier relaxation time from the GS to the ES, \( N_0 \) is the surface density of QDs, \( e \) is the dielectric constant of the QD material and \( \Gamma \) is the optical confinement factor. \( g_L \) is the peak material gain. According to Pauli's exclusion principle, the occupation probability in the quantum-dot ground state relates to the carrier density \( N \) in the QD by \( f = N/N_0 \) [5] where \( w_0 \) is the size of the QD. The average signal photon density \( S_{av} \) is given by [6]

\[
S_{av} = \left[ \frac{(G - 1)(1 - R_f)(1 + R_g) G_s}{\left(1 - \sqrt{R_f R_g}\right)^2 + 4 \sqrt{R_f R_g} \sin^2 \Phi} \right] \frac{P_{in} L_w}{\hbar \omega_0 D L g_c} \tag{11}
\]

Where \( P_{in} \) is the input signal power, \( n_g \) is the group refractive index, \( h \) is the normalized Plank’s constant, \( w_0 \) is the peak frequency, \( D \) is the width of the active layer, \( L \) is the cavity length, \( c \) is the free space light speed. Note that the Fabry-Perot amplifier gain \( G \) is given by [7]

\[
G = \frac{(1 - R_f)(1 - R_g) G_s}{\left(1 - \sqrt{R_f R_g}\right)^2 + 4 \sqrt{R_f R_g} \sin^2 \Phi} \tag{12}
\]

\( R_f \) is the front mirror reflectivity, \( R_g \) the back mirror reflectivity. \( \Phi \) is the phase angle while \( G_s \) is the single-pass gain of the structure, given by [7]

\[
G_s = \exp \left[ (g_p \Gamma - a_{\text{tot}}) L \right] \tag{13}
\]

Note that \( a_{\text{tot}} \) is the loss coefficient. The carrier dynamics described by the rate Equations are related only to electrons in the conduction band while hole dynamics can be neglected due to their larger effective mass [4]. In addition, typical values of the material parameters in Table 1 [5] for ZnSe/ZnS system where \( (E_g = 2.8 \text{ eV}, m_e = 0.17 m_0 \text{ and } m_v = 0.60 m_0) \) for ZnSe and \( (E_g = 3.68 \text{ eV}, m_e = 0.39 m_0 \text{ and } m_v = 0.49 m_0) \) for ZnS.

Rate equations model are solved at steady state case using the expression of the average signal photon density \( S_{av} \), Equation (11). The noise added to the signal during the amplification process is a fundamental property for every kind of amplifiers. The noise characteristics of an amplifier are quantified by a parameter called noise figure, when the shot noise part is taken into account, the amplifier noise figure can be written as [7].

\[
F_s = \frac{2n_{sp}(G - 1)}{G + (1/G)}
\]

The spontaneous emission factor \(n_{sp}\) is given by [8]

\[
n_{sp} = \frac{\Gamma e(w)}{[\Gamma G(w)]} - a_{int}
\]

4. Results and Discussion

Using quantum box model we calculate QD energy levels for conduction and valence bands and then it is used to calculate linear absorption coefficient, linear emission coefficient and net gain. The barrier layer thickness is 20 nm while the thickness of the clad layer is 75 nm, see Figure 2. All calculations are done at \(\tau_{in} = 0.1\) ps [3] and carrier density \(2 \times 10^{24} m^{-3}\). Also we calculate the small signal gain for structures contain one and six layers. Gain coefficients are calculated using Equation (7) for several values of input power.

Figure 3 shows a comparison between the linear absorption and emission coefficients where a multi-peaks appear for ground and excited state transitions. One can refers to the higher emission value compared to that of absorption which results from lower transparency value for this structure. The net gain is shown in Figure 4, where a double peak can also be seen. This is very important in some applications. For example, this can be used in long haul optical transmission. The reason for this double emission is reasoned to finite ground state relaxation time, which brings ground state emission to a constant value after the excited state threshold [10]. Figure 5 shows the effect of intraband relaxation time \(\tau_{in}\) where a higher gain is obtained at longer intraband time. Gain of the highest peak increases by \(\sim 4.5\) time when \(\tau_{in}\) increases from 0.1 ps to 0.5 ps. Really, intraband relaxation time controlled the transition between intersubband thus one can use this property to work with the same structure at higher gain by choosing the subbands that occur between them. Also, one can refers to the somewhat increase between the ground and excited peaks with intraband relaxation time.

Rate equations are then solved at steady state, using the parameters listed in Table 1, the QD-SOA characteristics are examined. Small-signal gain spectrum of this QD-SOA is shown in Figure 6. These gain values are comparable to that obtained by Ben-Azra [9]. Note that it is obtained here at a lower current value. So, this is a good modification. The effect of QD layer is also examined where the gain increases with QD layers as shown in Figure 7. Figure 8 shows the output power calculated as a function of carrier density with input power is taken as a parameter. Including the shot noise part, the noise figure spectrum is shown in Figure 9, while the noise figure curve at different carrier densities is shown in Figure 10 from the last two figures one can refers to the lower noise accompanied with this amplifier while the last three figures shows the properties of ZnSe/ZnS QD-SOA which is a good results to use it in applications.
