ABSTRACT

We consider a simple model of carbon nanotubes (CNTs) subject to external electric field $E(t)$. Using a tight-binding approximation for the description of energy bands of CNTs, together with the standard Boltzmann transport equation and constant relaxation time, we predict the effect of self-induced transparency and absolute negative conductivity. The predicted effects may be useful in diagnostics of carbon nanotubes as well as in the amplification and efficiency conversion of electromagnetic signals.

Keywords: Carbon Nanotubes; Electric Field; Electric Current Density; Negative Differential Conductivity

1. Introduction

The electrical transport properties of carbon nanotubes (CNs) have been the subject of much research ever since the discovery by Iijima [1] of the quasi-one-dimensional monomolecular structures. This may be due to their abilities to exhibit Bloch oscillations [2-5] at moderate electric field strengths. This oscillatory response makes CNs inherently nonlinear and as such can perform varieties of transport phenomena. Under different conditions of an external electric field, an electron is predicted to reveal a variety of physical effects such as Bloch oscillations, self-induced transparency, negative differential conductivity, absolute negative conductance [4], etc.

In this paper we study theoretically two phenomena in CNs, which are self-induced transparency and absolute negative conductance for the following cases respectively:

1) When the CNs is exposed to an a. c. electric field i.e. $E(t) = E_o \cos \omega t$.

2) When the CNs is exposed to an a. c. and d.c electric field i.e. $E(t) = E_o + E_i \cos \omega t$.

2. Theory

Following references [3,4] and using the approach similar to reference [6], we consider a response of electrons in an undoped achiral single-wall carbon nanotubes subject to an external electric field.

$$E(t) = E_o + E_i \cos \omega t$$ (1)

We use the semiclassical approximation in which $\pi$-electrons are considered as classical particles with dispersion law extracted from the quantum theory in the tight-binding approximation [4].

Considering the hexagonal crystalline structure of zig-zag and armchair CNTs within tight binding approximation, the dispersion relation is given as [4] respectively,

$$\epsilon_e(p_z) = \pm \gamma_o \left[ 1 + 4 \cos \left( ap_z \right) \cos \left( \frac{a}{\sqrt{3}} s \Delta p_\phi \right) \right]^{1/2}$$ (2)

$$\epsilon_i(p_z) = \pm \gamma_o \left[ 1 + 4 \cos \left( ap_z \right) \cos \left( \frac{a}{\sqrt{3}} s \Delta p_\phi \right) \right]^{1/2}$$

*Corresponding author.
where $y_0 \approx 3.0$ eV is the overlapping integral, $p_z$ is the axial component of quasimomentum, $\Delta p_z$ is the transverse quasimomentum level spacing and $s$ is an integer. The expression for $a$ in Equation (2) is given as $a = 3b/2h$ with the C-C bond length $b = 0.142$ nm and $\hbar$ is the Planck’s constant, we shall assume $\hbar = 1$. The $-$ and $+$ signs correspond to the valence and conduction bands, respectively. Due to the transverse quantization of the quasi-momentum, its transverse component can take $n$ discrete values, $p_x = s \Delta p_x = \pi \sqrt{3} s / a n$ ($s = 1, \ldots, n$). Unlike transverse quasimomentum $p_x$, the axial quasimomentum $p_z$ is assumed to vary continuously within the range $0 \leq p_z \leq 2 \pi / a$, which corresponds to the model of infinitely long CNT ($L = \infty$). This model is applicable to the case under consideration because of the restriction to the temperatures and/or voltages well above the level spacing [4]. We assume that there is no inter band transition or transition between different states i.e. $k_B T > \varepsilon_c, \Delta \varepsilon$, where $k_B$ is Boltzmann constant, $T$ is the temperature, $\varepsilon_c$ is the Fermi velocity and $L$ is the carbon nanotube length [6].

Proceeding as in 4, we employ Boltzmann equation with a constant relaxation time

$$
\frac{\partial f(p,t)}{\partial t} + eE(t) \frac{\partial f(p)}{\partial p} = \left[ f_e - f_o(p) \right] / \tau
$$

(4)

where $e$ is the electron charge, $f_o(p)$ is the equilibrium distribution function, $f(p,t)$ is the distribution function, and $\tau$ is the relaxation time. The electric field $E(t)$ is applied along CNTs axis. In this problem the relaxation term $\tau$ is assumed to be constant. The justification for being constant can be found in [3]. The relaxation term of Equation (3) describes the effects of the dominant type of scattering (e.g. electron-phonon and electron-twistons) [3]. We have noted that the distribution function $f(p,t)$ is periodic with a period $2 \pi / a$.

Expanding the distribution functions of interest in Fourier series as;

$$f_o(p) = \Delta p_z \sum_{s=1}^{n} \delta (p_z - s \Delta p_z) \sum_{n} f_n e^{i n p_z} \tag{5}
$$

and

$$f(p,t) = \Delta p_z \sum_{s=1}^{n} \delta (p_z - s \Delta p_z) \sum_{n} f_n e^{i n p_z} \mathcal{D}_o(t) \tag{6}
$$

where the coefficient, $\delta \delta(x)$ is the Dirac delta function, $f_n$ is the coefficient of the Fourier series and $\mathcal{D}_o(t)$ is the Fermi velocity and $p_c$ is the carbon nanotube. We determine the electron-phonon and electron-twistons [3]. We have noted that the distribution function $f(p,t)$ can be expanded in the analogous series with coefficients as follows

$$f_{rs} = \frac{2 \pi}{a} \int_{-\infty}^{\infty} \frac{e^{-iap_z}}{1 + \exp(e \epsilon_p / k_B T)} dp_z \tag{7}
$$

Substituting Equations (5) and (6) into Equation (4), and solving with Equation (1) we obtain

$$\mathcal{D}_o(t) = \sum_{k=-\infty}^{\infty} \sum_{\omega=-\infty}^{\infty} J_k (\beta \Omega) J_k (\beta \Omega) \exp(i \epsilon \omega) \tau \tag{8}
$$

where $\beta = e a E_o / \omega$, $J_k (\beta \Omega)$ is the Bessel function of the $k$th order and $\Omega = e a E_o$ for zigzag CNTs and $\Omega = e a E_o / \sqrt{3}$ for armchair CNTs.

We determine the surface current density as

$$j_z = \frac{e^2}{2 \pi \hbar} \int f(p) \nu_z(p) \frac{d^2 p}{d p_z^2} \tag{9}
$$

and the integration is carried over the first Brillouin zone. We consider the relation $\nu_z (p_z, s \Delta p_x, \mathcal{D}_o(t))$ in Fourier series with the coefficients defined similar to Equation (7).

Substituting Equations (6) and (8) into (9) we find the current density for the CNs after averaging over a period of time $\tau$, as

$$j_z = \frac{8 e \gamma_0}{\sqrt{5} \pi a} \sum_{n} \sum_{r} \sum_{s} \sum_{\omega} J_1 (\beta \Omega) (\beta \omega) \tau \tag{10}
$$

From Equation (10) we obtain
If \( k \omega \tau \gg \Omega \tau \) and \( \omega \tau \gg 1 \), Equation (11) takes the form

\[
J_z = \frac{8e\gamma_0}{\sqrt{3h\pi e}} \sum_{r=1}^{\infty} \left[ \frac{J_0^2(\beta)}{1 + (\Omega \tau)^2} - \frac{2}{(\omega \tau)^2} \sum_{k=1}^{\infty} \frac{J_0^2(\beta k^2)}{(k^2)^2} \right] \Omega \tau \sum_{r=1}^{\infty} f_r e_{r\pi} \tag{12}
\]

where \( \beta = (\varepsilon_0 E_t) / \omega \), \( J_0(\beta) \) is the Bessel function of the zeroth order.

From Equation (12) it is seen that near the zeros of \( J_0(\beta) \) and \( k \omega \tau \gg 1 \), the CNTs exhibit absolute negative resistance in the transparency regions. That is, the low frequency oscillations are amplified in these regions. This phenomenon is called absolute negative conductivity and was first observed by Kryuchkov et al. [6].

In the limiting case of \( \omega \tau \gg 1 \), \( E_0 = 0 \), we find that the current density for the CNTs is

\[
J_z = \frac{8e\gamma_0}{\sqrt{3h\pi e}} \sum_{r=1}^{\infty} r J_0(\beta) \sin(\beta \sin \omega t) \sum_{r=1}^{\infty} f_r e_{r\pi} \tag{13}
\]

From Equation (13) at each zero of the \( J_0(\beta) \) function the current density vanishes and the CNTs become transparent. See also Ignatov et al. [7].

### 3. Results and Discussion

Equations (12) and (13) describe the theory of electron transport in the presence of an external electric field \( E(t) \). We assume that the equations do not take into account both interband transitions and quantum-mechanical corrections to the intraband motion or resonant transitions inherent in the CN lattice. To estimate the restriction on the fundamental frequency necessary for resonant transitions to be negligible, we apply a general approximate relation for the electron state density in a CNT [3,8] that establishes the low-frequency edge \( \bar{\omega} \) of the optical transition band in metallic CNTs: \( \bar{\omega} = 3 \gamma \sqrt{b} / 2hR \), where \( R \) is the CNTs radius. This condition is decisive for the applicability of the developed theory in CNTs. As the CNTs radius increases, the upper limit for the fundamental frequency is shifted to the red. Thus, CNTs with not too large radii are of the most interest. Another limitation is related to the strength of the driving field where interband tunneling is negligible: the Stark frequency corresponding to this field must be smaller than the conduction zone bandwidth \( E_1 < \gamma \sqrt{b} \) [9]. Otherwise, the bond of \( \pi \)-electrons with the crystalline lattice breaks down, resulting in a strong Stark broadening and making the dispersion law ((2) and (3)) inapplicable. For the condition of high-frequency fields \( E(t) = E_0 \cos \omega t \), an analytical expression for the current density was obtained in Equation (13). Figures 1 and 2 illustrate the graphs of \( J_z / J_0 \) on \( \beta \) for (12, 0) metallic zigzag and (10, 10) metallic armchair CNTs calculated by Equation (13). From the figure it is seen that the amplitude of the current density oscillates with increasing amplitude of the high frequency and in the zeros of the \( J_0(\beta) \) function or when \( \beta = \text{eigen} \text{values} \) the CNTs. However, when the CNTs is exposed to an a.c. and d.c electric fields, i.e. \( E(t) = E_0 + E_t \cos \omega t \) for \( k \omega \tau \gg \Omega \tau \) and \( \omega \tau \gg 1 \), we obtained expression (12) which is an indication for absolute negative conductivity i.e. current flows against the applied d.c field. See Figure 2. Figure 2 elucidates the dependence of \( J_z / J_0 \) on \( \beta \) for (12, 0) metallic zigzag and (10, 10) metallic armchair CNTs obtained via the calculation of Equation (12). In the low limit of \( \beta \), we observed that as \( \beta \) increases, the normalized current \( J_z / J_0 \) decreases and at a certain value e.g., \( \beta = \beta_{\text{min}} \) the normalized current reaches a minimum value \( (J_z / J_0)_{\text{min}} \). Thus, we predict the region with absolute negative conductivity (ANC). Also we note that such state will be unstable and will lead to CNTs segmentation into domains. The region of absolute negative conductivity decreases when external electric field increases. We noted that due to the high density of states of conduction electrons in carbon nanotubes and the specific dispersion law inherent in hexagonal crystalline structure result in a uniquely higher current densities for the metallic zigzag CNTs than the me-
tallic armchair CNTs.

4. Conclusion

In conclusion, using the solution to the Boltzmann transport equation with constant relaxation time, we report on a theoretical analysis of a simple model of carbon nanotubes (CNTs) subject to an external electric field. We predict the effect self-induced transparency and absolute negative conductivity. The predicted effects may be useful in diagnostics of carbon nanotubes as well as in the amplification and efficiency conversion of electromagnetic signals. We noted that the metallic zigzag CNT has higher current density than the metallic armchair CNT. This is attributed to the fact that the metallic zigzag CNT has higher density of states of conduction electrons than the metallic armchair CNT. Another reason for the metallic zigzag CNT to exhibit higher current density than the armchair is due to its dispersion law which is derived from the hexagonal structure.
