Abstract

Need for developing efficient non-destructive damage detection procedures for civil engineering structures is growing rapidly. This paper presents a methodology for detection and quantification of structural damage using modal information obtained from transfer matrix technique. Vibration characteristics of beam-like structure have been determined using the computer program developed based on the formulations presented in the paper. It has been noted from reported literature that detection and quantification of damage using mode shape information is difficult and further, extraction of mode shape information has practical difficulties and limitations. Hence, a methodology for detection and quantification of damage in structure using transfer matrix technique based on the changes in the natural frequencies has been developed. With an assumption of damage at a particular segment of the beam-like structure, an iterative procedure has been formulated to converge the calculated and measured frequencies by adjusting flexural rigidity of elements and then, the intersections are used for detection and quantification of damage. Eventhough the developed methodology is iterative, computational effort is reduced considerably by using transfer matrix technique. It is observed that the methodology is capable of predicting the location and magnitude of damage quite accurately.

Keywords: Frequency, Mode Shape, Transfer Matrix, Damage Detection, Quantification

1. Introduction

The need for development of an efficient procedure for non-destructive structural damage detection is increasing in order to assess the integrity and serviceability of existing structures. This has led to continued research to develop methods that could identify changes in vibration characteristics of a structure. These methods are based on the fact that modal parameters (notably frequencies and mode shapes, and modal damping) are functions of the physical properties of the structure (mass, damping, and stiffness). Any change in the physical properties, such as reduction in stiffness resulting from cracking or loosening of a connection, will cause detectable change in the modal properties. Various methods have been employed by researchers all over the world for damage detection of structural systems, in frequency domain.

Perhaps, the first research article on damage detection us-

ing vibration measurements was by Lifshitz and Rotem [1] where the change in the dynamic moduli was related to the frequency shift and proposed as indicator of damage in particle-filled elastomers. Cawley and Adams [2] are the first researchers to give a formulation for damage detection based on change in frequency of an undamaged and damaged state of a structure. The systematic use of mode shape information was proposed in [3] for localizing of structural damage without the use of a prior finite element model (FEM) by using the modal assurance criteria (MAC) to determine the level of correlation between modes from the test of an undamaged space shuttle orbiter body flap. Yuen [4] examined changes in the mode shape and mode-shape-slope parameters to simulate the reduction of stiffness in each structural element and compared predicted changes with the measured changes to determine the damage location. Ismail *et al.* [5] demonstrated that the frequency drop caused by an

opening and closing crack is less than that caused by an open crack. This property is a potentially large source of error that is considered by few of the researchers using frequency changes. A simple and easy method for one-dimensional structures by representing crack using a spring that connects the two half components was presented by [6]. The natural frequencies were expressed as functions of the crack depth and location. Hearn and Testa [7] developed a damage detection method using frequency shift of a structure due to damage. The frequency sensitivity method combined with internal-state-variable theory to detect damage in composites was used in [8]. They presented a damage indicator which is capable of detecting damage due to 1) extensional stiffness changes caused by matrix micro-cracking and 2) changes in bending stiffness caused by transverse cracks in the 90-degree plies. An experimental study on the sensitivity of the measured modal parameters of a shell structure was conducted in [9] to damage in the form of a notch. A method for the detection of the existence and location of structural damage using the identified eigen solution together with properties of the eigenvalue problem was proposed in [10].

Slater and Shelley [11] presented a method based on frequency-shift measurements to detect damage in a smart structure by using the theory of modal filters to track the frequency changes over time. Narkis [12] deduced a closed-form solution for the crack position, as function of the frequency shift of two modes of the same mechanical model and located the crack from measuring either bending or axial frequencies of two modes only. A transfer matrix technique was used in [13] to detect damage for beam like structures. Ratcliffe [14] developed a technique for identifying the location of structural damage in a beam using modified Laplacian Operator on mode shape data. A sensitivity- and statistical- based method to localize structural damage by direct use of incomplete mode shapes was presented in [15] and [16]. A numerical study of damage detection using the relationship between damage characteristics and the changes in the dynamic properties was presented by [17]. It was found that the rotation of mode shape is a sensitive indicator of damage localisation. Another damage localisation method based on changes in uniform load surface (ULS) curvature was developed by Wu and Law [18]. A procedure using gap smoothing method was proposed in [19] wherein local features in vibration curvature shapes were extracted using a localized curve fit (i.e., smoothing). Alvandi and Cremona [20] reviewed usual vibration-based damage identification techniques for structural damage evaluation. With the help of a simply supported beam with different damage levels, the reliability of these techniques was investigated by using only few mode shapes and/or modal frequencies of the structure that can be easily obtained by dynamic tests and con-

cluded that broadly the detection judgement depends on a threshold level of damage.

1.1. Detection of Damage Using Mode Shape Information

From the review of literature, it is found that the vibration data such as frequency and mode shape are very important parameters for detecting the damage in structures and a number of research works was carried out on detection of damage using frequency or mode shape. But, there is no confirmation on superiority of any method over the others. Though, changes in mode shape are much more sensitive to local damage compared to changes in frequency, use of mode shape information is restricted because 1) lower modes (usually measured from vibration tests of large structure) may not significantly reflect the local damage, 2) extracted mode shapes are prone to environmental noise and 3) number of sensors and the choice of sensor location may have a crucial effect on accuracy of damage detection. So, a detailed investigation has been carried out by the authors to assess the influence of location and degree of damage on mode shape. It is found that 1) displacement mode shapes are sensitive to damage and the mode shape changes with damage, 2) though higher modes are more predominant in showing the shift in mode shape displacements due to damage in the structure, lower modes may not significantly reflect the damage, 3) shift in mode shape largely depends on the location of damage and the mode considered. Higher mode will magnify the shift in mode shape, if the damage location does not fall near the zero-displacement points, 4) any shift in mode shape of a damaged structure with respect to the mode shape of undamaged structure may lead to an interpretation of damage in that location, and in most of the cases, it may go wrong. Further, for higher modes, if the damage is located at a location where zero displacement occurs in that particular mode, shift in mode shape will be reflected in place other than the place where damage has really taken place, 5) Shift in mode shape is predominant in higher modes than in the lower modes. It may show a number of locations with shift in mode shape with respect to undamaged mode shape which may lead to misinterpretation of location of damage. So, it can be stated that mode shape information alone can not provide correct information on detection of damage in the structure unless it is treated otherwise, and 6) it is very difficult to quantify damage accurately from mode shape information alone. Further studies can be seen elsewhere [21,22].

Though significant damage might cause very small changes in natural frequency (particularly for large structures), natural frequencies are easy to be measured and are less influenced by environmental noise. The choice of using the natural frequency as a basic vibration

characteristic for damage detection is the most attractive one due to the fact that the natural frequencies of a structure can be measured at one single location in the structure, thus rendering a means for a rapid and global technique. Further, it is observed that studies related to the extension of transfer matrix method for detection of damage are very few. Hence, in this study, a methodology for detection of damage in structures using transfer matrix technique has been proposed based on change in natural frequency. The extent of research work carried out towards quantification of damage is considerably less compared to studies on localisation of damage. In view of this, a methodology has been developed in this study for detection and quantification of damage using transfer matrix method based on modal frequencies obtained from a damaged structure. Transfer matrix method [23] is used in this study because of its versatility and ease with which it can be applied to a structure of either uniform or non-uniform cross section and under a variety of boundary conditions such as simple support, cantilever support, and even for beam on elastic foundation. Moreover, for a methodology based on an iterative algorithm, as proposed in this study, transfer matrix method is very useful and easy to handle compared to FE formulation. Theoretical developments of the methodology for detection and quantification of damage are presented first, followed by detailed numerical studies to demonstrate the efficacy of the proposed method.

2. Transfer Matrix Method for Obtaining Modal Parameters

For computing plane flexural vibrations of a straight beam using transfer matrix method, the beam section is modelled by discrete uniform structural elements interconnected at the nodal points. Using the conventional assumption of a mass-less beam, the inertia effects of the beam element are dynamically represented by two lumped masses at both ends of the element (as shown in Figure 1).

Each individual beam is considered to be of individual homogenous material property and geometry which can be represented by area moment of inertia and Young's modulus of that particular element. Two displacements, viz., vertical deflection (η) and rotation (ϕ) and the cor-

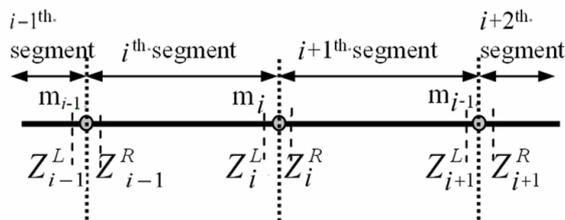

Figure 1. Beam with concentrated masses.

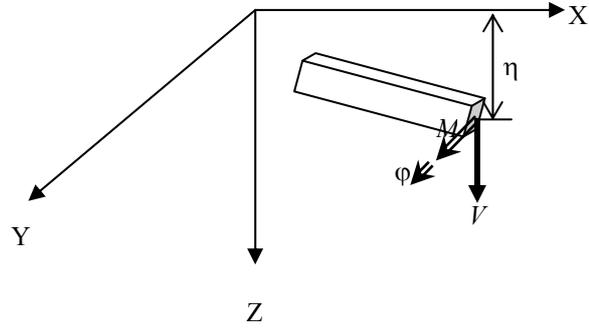

Figure 2. Sign convention for state array variables of beam element.

responding forces viz., shear force (V) and bending moment (M) are considered for describing the state array variables at each section and the sign convention of the state array variables is shown in Figure 2.

The equilibrium between sections i and $i-1$ of an element will be maintained by

$$V_i^L - V_{i-1}^R = 0 \tag{1}$$

$$M_i^L - M_{i-1}^R - V_i^L l_i = 0 \tag{2}$$

where the superscript L and R stands for left and right side of a section respectively.

Two more equations that are required for solving the problem can be obtained from compatibility conditions and the final equations can be expressed as

$$\eta_i^L = \eta_i^R + l_i \phi_{i-1}^R + \frac{l_i^2}{2(EI)_i} M_{i-1}^R + \frac{l_i^3}{6(EI)_i} V_{i-1}^R \tag{3}$$

$$\phi_i^L = \phi_{i-1}^R + \frac{l_i}{(EI)_i} M_{i-1}^R + \frac{l_i^2}{2(EI)_i} V_{i-1}^R \tag{4}$$

$$M_i^L = M_{i-1}^R + l_i V_{i-1}^R \tag{5}$$

$$V_i^L = V_{i-1}^R \tag{6}$$

and can be expressed in matrix form as,

$$\begin{bmatrix} -\eta \\ \phi \\ M \\ V \end{bmatrix}_i^L = \begin{bmatrix} 1 & l & \frac{l^2}{2EI} & \frac{l^3}{6EI} \\ 0 & 1 & \frac{l}{EI} & \frac{l^2}{2EI} \\ 0 & 0 & 1 & l \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} -\eta \\ \phi \\ M \\ V \end{bmatrix}_{i-1}^R \tag{7}$$

So, from Equation (7), the field matrix (F_i) connecting Z_i^L with Z_{i-1}^R can be expressed as

$$Z_i^L = F_i Z_{i-1}^R \tag{8}$$

The point matrix (P_i) connecting Z_i^R with Z_i^L is found by using continuity of deflection, slope and moment across the concentrated mass m_i ,

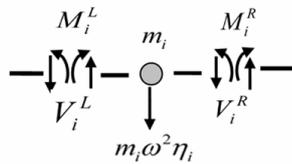

Figure 3. Free-body diagram of mass m_i .

$$\eta_i^R = \eta_i^L; \phi_i^R = \phi_i^L \text{ and } M_i^R = M_i^L \tag{9}$$

The vibrating mass, however, introduces the inertial force which causes discontinuity in shear. The free-body diagram shown in Figure 3 yields a relation from simple equilibrium considerations as:

$$V_i^R = V_i^L \pm m_i \omega^2 \eta_i \tag{10}$$

(in formulation, a particular sign convention has been followed)

Equations (9) and (10) can be expressed in matrix form as:

$$\begin{bmatrix} u_{12}^n & u_{14}^n \\ u_{32}^n & u_{34}^n \end{bmatrix} \begin{bmatrix} -\eta \\ \phi \\ M \\ V \end{bmatrix}_i^R = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ m_i \omega^2 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} -\eta \\ \phi \\ M \\ V \end{bmatrix}_i^L \tag{11}$$

$$Z_i^R = \mathbf{P}_i Z_i^L \tag{12}$$

By combining both field and point matrices, relation between the state vectors of adjacent ends (i and $i-1$) can be obtained as

$$Z_i^R = \mathbf{P}_i \mathbf{F}_i Z_{i-1}^R \tag{13}$$

2.1. Transfer Matrix for Frequency Determinant

The transfer matrix method can be applied to solve more complicated problems by considering a beam that is made up of piecewise uniform mass-less elements, with masses concentrated at discrete points. If a structural element is made up of n segments (between the ends 0 to n), relationship between the state vectors at the extreme ends (0 and n) of the beam can be obtained as

$$Z_n = \mathbf{F}_n \mathbf{P}_{n-1} \mathbf{F}_{n-1} \dots \mathbf{P}_4 \mathbf{F}_4 \mathbf{P}_3 \mathbf{F}_3 \mathbf{P}_2 \mathbf{F}_2 \mathbf{P}_1 \mathbf{F}_1 Z_0 \tag{14}$$

$$Z_n = \mathbf{U} Z_0$$

Equation (14) can be written in full, as

$$\begin{bmatrix} -\eta \\ \phi \\ M \\ V \end{bmatrix}_n = \begin{bmatrix} u_{11}^n & u_{12}^n & u_{13}^n & u_{14}^n \\ u_{21}^n & u_{22}^n & u_{23}^n & u_{24}^n \\ u_{31}^n & u_{32}^n & u_{33}^n & u_{34}^n \\ u_{41}^n & u_{42}^n & u_{43}^n & u_{44}^n \end{bmatrix} \begin{bmatrix} -\eta \\ \phi \\ M \\ V \end{bmatrix}_0 \tag{15}$$

where the coefficients u_{11}^n to u_{44}^n are functions of circular frequency ω . Boundary conditions can be applied to the equations formulated from Equation (15) to arrive at the frequency determinant. For example, a beam (consists of n segments) with simply supported ends can be solved as follows:

The boundary conditions at simply supported ends are $\eta_n = 0, M_n = 0, \eta_0 = 0,$ and $M_0 = 0;$

By substituting these boundary conditions in Equation (15), the following relation can be obtained

$$u_{12}^n \phi_0 + u_{14}^n V_0 = 0 \tag{16a}$$

And,

$$u_{32}^n \phi_0 + u_{34}^n V_0 = 0 \tag{16b}$$

where u_{ij}^k is element of i^{th} row and j^{th} column of the transfer matrix which can be obtained by using Equation (15) and superscript k denotes the number of segments. The normal modes can be found for the system using the following procedure.

For a nontrivial solution of Equations (16a) and (16b), the determinant of the coefficients must be zero, that is

$$\begin{vmatrix} u_{12}^n & u_{14}^n \\ u_{32}^n & u_{34}^n \end{vmatrix} = 0 \tag{17}$$

The same procedure can be followed for other boundary conditions also. Since, the elements u_{ij} are functions of the circular frequency ω , this determinant serves to compute the natural circular frequencies. In view of the fact that a beam which possesses n segments will have $n-1$ discrete masses, the expansion of the frequency determinant leads to an equation of $n-1$ degree in ω^2 .

2.2. Numerical Procedure for Solution of Frequency Equation

In the preceding section, the matrix multiplications have been made by treating ω^2 as a free parameter. After applying the boundary conditions the resulting frequency equations are solved for ω^2 . For complicated systems, the algebraic solution would become complicated and furthermore, it would be very cumbersome to extract the roots. In such cases, it is advantageous to replace algebraic solution with numerical computation. For system with ' n ' segments with simply supported ends, the frequency determinant (as described in Equation 17) would become

$$\Delta = \begin{vmatrix} u_{12}^n & u_{14}^n \\ u_{22}^n & u_{24}^n \end{vmatrix} = 0 \tag{18}$$

If the matrix multiplication is carried out algebraically,

then the coefficients u_{12}^n , u_{14}^n , u_{22}^n and u_{24}^n and consequently the frequency condition would be complicated functions of ω^2 . The procedure adopted in practice, however, is to choose certain values for ω^2 and compute the corresponding values of the frequency determinant $\Delta(\omega)$. The value of the determinant Δ is then plotted against ω , the zero values of Δ occur at the natural circular frequencies of the system. This procedure has been adopted in the study for tracking of frequencies.

3. Determination of Frequency of a Structure Using Transfer Matrix Method

In this study, a computer program called **FREQ** has been developed based on the formulation presented in the preceding sections and the flow-chart of the program for obtaining frequencies of a structure, is shown in Figure 4. The formulations and the computer program have been validated by comparing the results of this study with those obtained using Finite Element Analysis (FEA). Table 1 gives the comparison of frequencies obtained by using transfer matrix method and FEA. From this table, it can be seen that the results of this study are in good agreement with those obtained using standard FEA package. For the validation study, a beam with 90 elements have been considered with Young's modulus (E) = 25×10^6 kN/m², moment of inertia (I) = 0.001333 m⁴ and cross sectional area (A) = 0.1 m².

As discussed in the preceding section, the determinant for the whole beam after incorporating the boundary conditions is computed for an assumed (initial) natural frequency. Then, an iterative procedure has been carried out by incrementing natural frequency to get the determinant of the transfer matrix. The frequency for which the determinant value is nearly zero, has been assigned as the natural frequency of the beam. The variation of the determinant of the transfer matrix for different modes of the beam is shown in Figure 5. For clarity, the determinant value (Δ) has been scaled down suitably after reaching a particular frequency. For example, for first, second and third natural frequencies, the determinant (Δ) of the transfer matrix is scaled down to $1/10^{\text{th}}$, $1/100^{\text{th}}$

Table 1. Comparison of frequency obtained using transfer matrix method and FEA.

Modes	Frequency (ω) in Hz
First mode	5.648 (5.670)
Second mode	22.564 (22.557)
Third mode	50.478 (50.306)
Fourth mode	88.108 (88.352)
Note: Results obtained from FEA are presented in brackets	

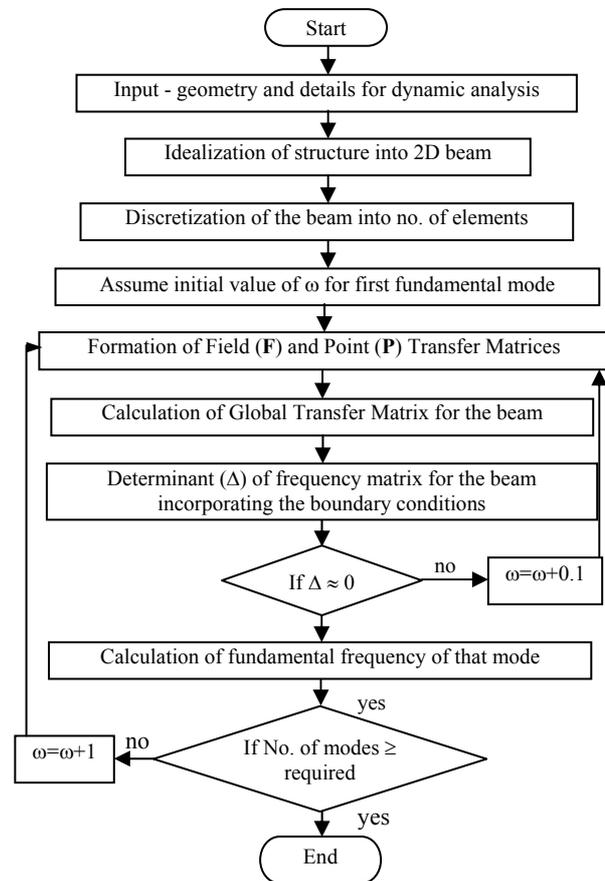

Figure 4. Flow-chart of computer program (FREQ).

and $1/500^{\text{th}}$ respectively. The frequencies corresponding to zero values of the determinant (Δ) represent the natural frequencies (ω) of the beam for different modes (as shown in Figure 5).

The central philosophy of detection of damage of beam like structure using transfer matrix formulation presented here, is to determine the reduction in flexural rigidity of one or more elements of the beam which would signify the existence of damage in the structure. In this context, question may arise that how far the frequencies of a structure are influenced by the damage in a particular element(s), in other words, what is the change in the determinant of transfer matrix with the change in flexural rigidity in one or more elements of the beam. In view of this, a study has been carried out to evaluate the frequency determinant by changing the magnitude and locations of the damaged element(s) to evaluate the influence of location and magnitude of damage on frequency of a structure. It is noticed that the frequencies corresponding to higher modes are influenced predominantly by change in flexural rigidity of one or more elements of the beam. For clarity, the changes in determinant values for the first two frequencies are shown in Figure 6. It is observed from the figure that by reducing

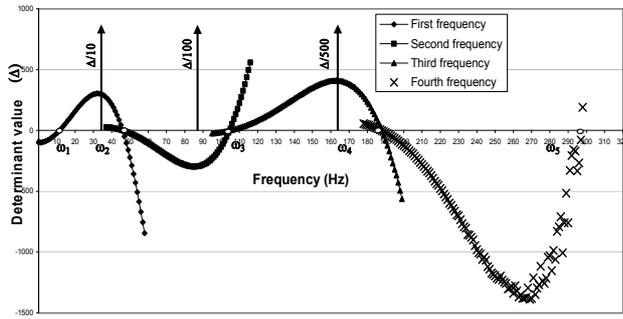

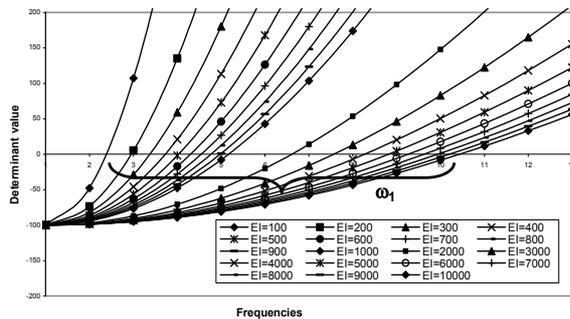

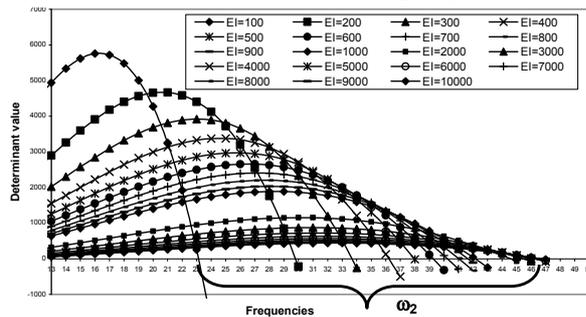

Figure 5. Variation of determinant of transfer matrix for different modes.

(a) For first fundamental frequency.

(b) For second fundamental frequency.

Figure 6. Variation of determinant with degree of damage (EI in kNm²).

flexural rigidity of a particular element of the beam considered in this study, frequency of the second mode varies over a wider range than that of the first mode. This signifies that the shift in frequency of second mode due to damage is more predominant than that in the first mode frequency. It is also noted from the study that this phenomenon is valid for next higher modes.

4. Results and Discussions

Though the transfer matrix technique can easily be applied to any type of structure with appropriate boundary conditions, a beam like structure with simply supported ends is considered in this study to demonstrate the efficacy of the methodology and its accuracy. The material

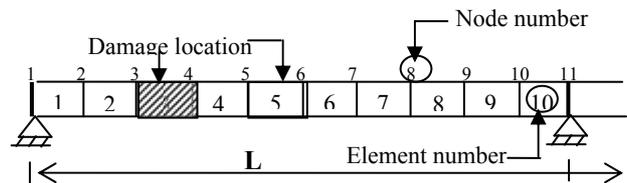

Figure 7. A typical beam like structure with elements and node numbers.

and sectional properties of the beam considered in this study are same as that mentioned for validation study. It is true that a finer division of a structure would lead to a more precise result, but for demonstrating the methodology proposed in this study, a beam like structure with 10 elements (as shown in Figure 7) has been considered for better representation, faster computation and clarity. Another reason behind considering less number of elements in this study is that for single-spread damage case, coarser mesh can occupy maximum amount of damage in minimum number of elements which would reduce the computation time without sacrificing the efficiency.

4.1. Solution Procedure for Detection of Damage Using Change in Frequencies.

The methodology proposed in this study, uses natural frequency information obtained from the transfer matrix formulations, for detection, quantification and localization of damage. A beam with known location and magnitude of damage has been analysed for extracting the natural frequencies. The existence of orthogonal damage in a beam structure can be simulated numerically via a change in flexural rigidity (EI) in a particular beam element. Such changes or reduction in flexural rigidity would result in change or decrease in the natural frequencies of the system. Through the measurement of the system natural frequencies of the structure, the location and magnitude of the damage can be determined. Assuming that flexural rigidity of all the segments of the system are known, the dynamics of the system can be obtained by the numerical model described in the preceding section.

When damage has occurred in a certain beam segment, it can be detected through the changes in the system natural frequencies. For the system containing damage, the iterative procedure starts with an assumption that the damage is located at the first beam element. The corresponding flexural rigidity of the element is adjusted until the first natural frequency of the system is matched with the measured one. The process is then continued with the second segment of the structure and the first natural frequency of the system is again matched by adjusting the flexural rigidity of the second element. The process is repeated for all the segments of the structure. The same

technique is followed for other modes which can be measured through vibration testing. The location and magnitude of the damage of the structure can be identified by the intersection of various rigidity-versus-damaged beam element location curves. The intersection of the curves obtained for different modes represent damage locations and magnitudes (flexural rigidity) which caused the changes in the system natural frequencies. Flow-chart of the computer program developed in this study based on the formulation described above for detection and quantification of structural damage is shown in Figure 8.

4.2. Case Study

For a numerical simulation, a beam is considered where the geometric and material properties are same as that mentioned for validation study. It is significant to mention that, in this study, 1) single damage does not represent only one damage (one crack) in the entire structure which is not practical in real structure too. As the formulation states, an element in the structure can be chosen to take a considerable length of the structure. The proposed methodology would show the location and magnitude of damage in an element considering all the damages occurred in that particular element which can be used for further discretisation, if required, to arrive at more particular locations. 2) It is also noticed that the most of the reported methodologies for damage detection perform well when degree of damage is very severe. But, in real practice, when large damages are already included in the structure, a sophisticated methodology for damage detection is not required, rather it can be located either by visual observation or simple inspection techniques. So, in this study, low levels of damages are considered to illustrate the methodology and to check its acceptability. 3) For all the case studies presented here, frequencies corresponding to only first four modes are considered because more number of modes may not be available from the field experiments. It is always a challenging problem to detect and quantify damage from less number of modes. Further, consideration of more number of modes is computationally expensive too.

Three levels of damage in two different locations have been studied separately, i.e., a beam with 10%, 20% and 30% damage in an element near support (3rd element as shown in Figure 7) and near centre (5th element as shown in Figure 7) respectively. These studies have been considered to examine the performance of the proposed methodology because it is known that the change in frequency with damage (reduction in flexural rigidity) of a structure greatly depends on the degree and location of damage.

Using the proposed methodology and computer pro-

gram developed based on the flow-chart shown in Figure 8, iterative study has been carried out for satisfying the frequencies corresponding to different modes of a damaged beam. Final flexural rigidities of each element along the length of the beam are obtained from the computer program and plotted for the cases mentioned above. It is observed that the true location and magnitude of the damage are identified by the intersection of the various rigidity versus element location curves. Cases with damage of 10% (remaining flexural rigidity of 29993 kNm²) in 3rd and 5th element are shown in Figure 9 and Figure 10 respectively. It is observed from Figures 9 and 10 that intersections of curves for different modes correctly indicate the damage locations (in 3rd and 5th element) with a remaining flexural rigidity of 30000 kNm².

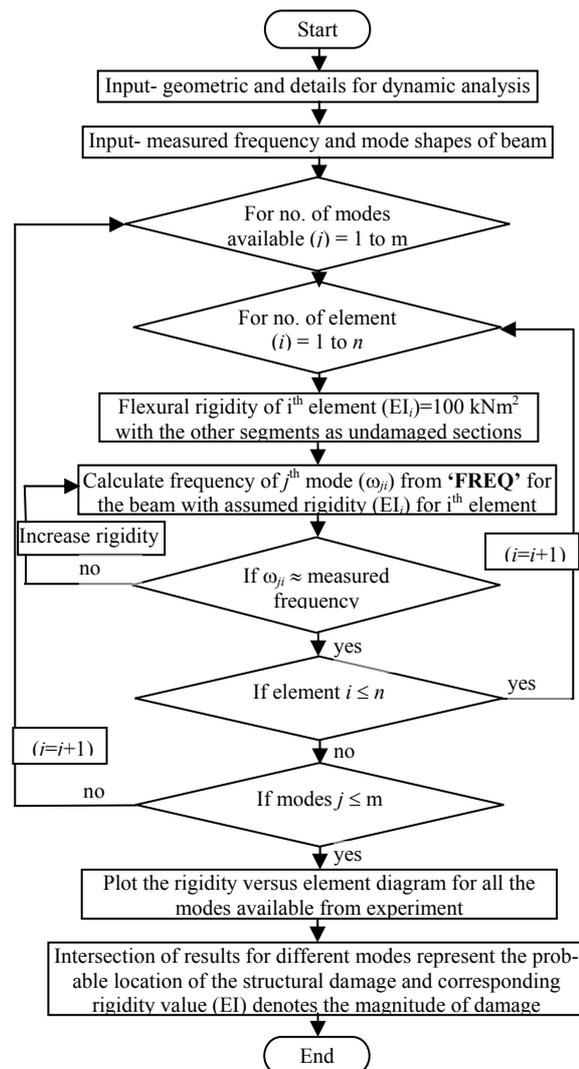

Figure 8. Flow chart for detection and localisation of structural damage.

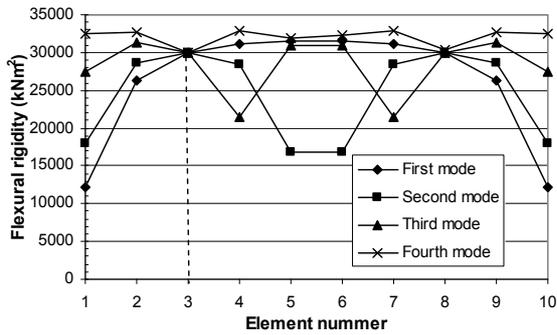

Figure 9. Flexural rigidity versus element diagram for 10% damage in 3rd element.

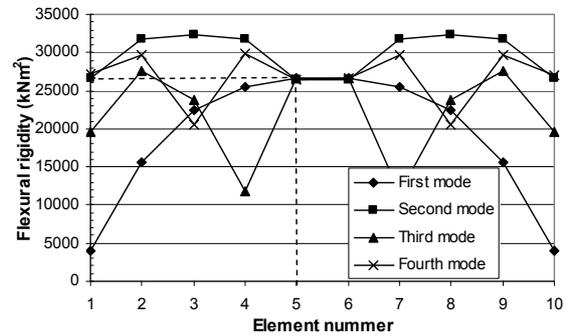

Figure 12. Flexural rigidity versus element diagram for 20% damage in 5th element.

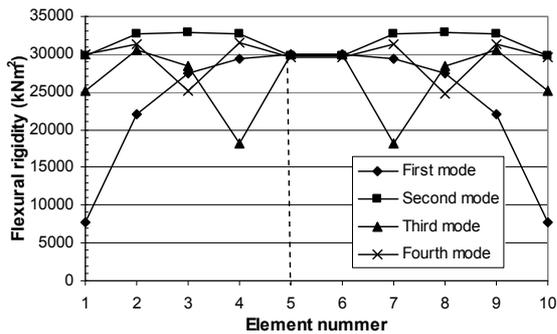

Figure 10. Flexural rigidity versus element diagram for 10% damage in 5th element.

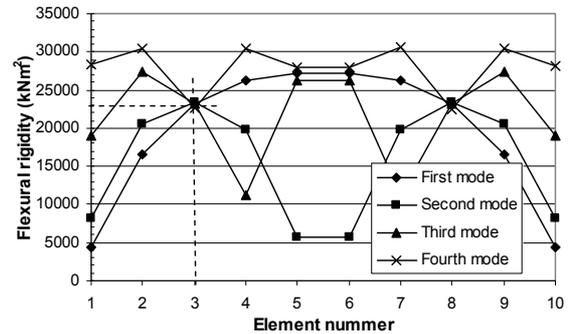

Figure 13. Flexural rigidity versus element diagram for 30% damage in 3rd element.

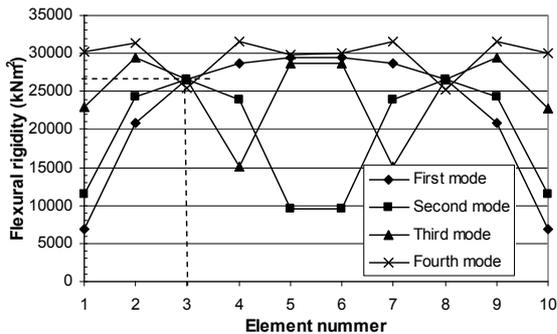

Figure 11. Flexural rigidity versus element diagram for 20% damage in 3rd element.

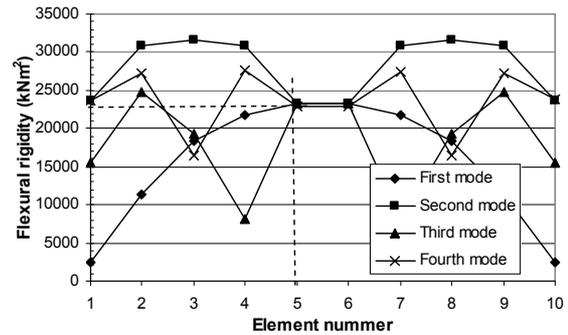

Figure 14. Flexural rigidity versus element diagram for 30% damage in 5th element.

Similarly, Cases with damage of 20% (remaining flexural rigidity of 26660 kNm²) and 30% (remaining flexural rigidity of 23328 kNm²) in 3rd and 5th element are shown in Figures 11-12 and Figure 13-14 respectively which indicate damage in the correct elements with a magnitude of 26500 kNm² (as shown in Figure 11 and Figure 12) and 23500 kNm² (as shown in Figure 13 and Figure 14), respectively.

It is important to note that the evaluated magnitudes of damage are quite close to the actual values.

In these studies discussed above, known degrees and locations of damages have been considered for validating

the methodology for detection and localisation of damage. It is found that the procedure is able to identify the location and magnitude of damage. Hence, this procedure can be adopted for detection and quantification of damage of structures using measured frequencies of first few modes. In this study, the problems are selected in such a way that both strengths and limitations of the proposed methodology can be examined. From the results shown in Figures 9-14, a few observations can be made as: 1) frequency based methodology proposed in this study can be used for localisation as well as quantification of damage, 2) since, the proposed methodology is based on only frequency information, structures with symmetrical boundary condition would always show two

possible locations of damage, and, 3) it is desirable to obtain the lowest measured frequency of a damaged structure with maximum possible accuracy to get an improved and more accurate estimation.

During the study, it is further observed that the proposed methodology is able to provide information about the state of damage and its location in a damaged structure, but the accuracy and reliability of the results (both localisation and quantification) also depends on correctness of information on the undamaged state. So, the proposed methodology would perform satisfactorily with a condition of availability of information (flexural rigidity) in its undamaged state. Hence, the study is further being extended to formulate a procedure which can be used for identification of damage when information about the undamaged state of a structure is not available, and it is being explored to check the efficacy and the suitable solutions (if any) for the proposed methodology with various levels of noise in modal data.

5. Concluding Remarks

The present paper addresses the methodology for detection, localisation and quantification of damage based on the formulations made using transfer matrix technique. First, the formulations and the computer program have been developed for obtaining the vibration characteristics of beam-like structures. The computer program has been validated by comparing the results of this study with those obtained using Finite Element Analysis (FEA) package. The results of this study are in good agreement with those obtained using standard FEA package. From the existing studies, it is noted that displacement mode shapes are sensitive to damage and higher modes show predominant shift in mode shape displacements due to damage in the structure. But, shift in mode shape largely depends on the location of damage and the mode considered and it is difficult to quantify damage from mode shape information. Hence, a methodology for detection, localisation and quantification of damage in structures has been proposed based on change in natural frequency obtained from transfer matrix technique. The existence of orthogonal damage in a beam structure can be simulated numerically through change in flexural rigidity (EI) in a particular beam element. For the system containing damage, an iterative procedure has been adopted by adjusting the flexural rigidity of the element such that computed frequency matches with the measured values. The location and magnitude of the damage of the structure can be identified by the intersection of the various rigidity-versus-element location curves. Studies have been presented by considering single spread-damage cases with different degrees and locations of damage to validate the accuracy, reliability and to identify the possible limitation of the proposed

methodology. It is found that the proposed methodology can localise and quantify damage in a structure with considerable accuracy.
