ABSTRACT

Background: In the recent years, various studies on clinical evaluation of systolic blood pressure recovery (SBPR) as a prognostic tool for diagnosing cardiovascular abnormalities in patients undergoing exercise test has become a subject of interest. The Purpose of this study is to evaluate the independent relationships of systolic blood pressure recovery (SBPR) with Cardiovascular Variables in healthy Urban adults.

Methodology: Normotensive subjects (157 nos.) of both the genders were performed cycle ergometer exercise at progressive incremental workloads until subjects reached 80% of their age-predicted maximum HR. Blood pressure (BP) was measured before exercise, during exercise, immediately after exercise and subsequently at 2-minute intervals until recovery to baseline. The ratio of third-minute SBP relative to first-minute post exercise SBP was used as the SBPR variable. Results: Our results indicated independent correlations (p < 0.05) between SBPR and age, resting HR, physical activity and cigarette smoking (r = 0.473; 0.192; −0.262; 0.102 respectively in males and r = 0.113; 0.315; −0.637; 0.104 respectively in females). BMI associated positively (r = 0.106; p < 0.01) with SBPR in males but not in females (r = 0.092), while WC was predictive of SBPR in females (r = 0.212; p < 0.01) but not in males (r = 0.005). Age in men and physical activity in females were the strongest predictors of SBPR. Conclusion: The present findings in which SBPR is associated with risk factors of cardiovascular abnormalities strengthen the previously reported significance of SBPR after exercise test as a prognostic tool for the evaluation of cardiovascular abnormalities. Additionally, it may help clinicians to define and interpret the mechanisms behind changes in post exercise SBP responses in adults in future investigations.

Keywords: Cycle Ergometer Exercise; Cardiovascular Variables; Systolic Blood Pressure Recovery

1. INTRODUCTION

In the recent years, various studies on clinical evaluation of systolic blood pressure recovery (SBPR) as a prognostic tool for diagnosing cardiovascular abnormalities in patients undergoing exercise test has become a subject of an interest [1-5]. In these studies, a delay in SBPR is correlated with an increased risk of cardiovascular diseases such as coronary artery disease, angina pectoris, hypertension, acute myocardial infarction and stroke. The SBPR is evaluated using a very useful and readily obtainable parameter, the third minute SBP ratio, which is defined as the ratio of SBP in 3 min of recovery relative to either the peak-exercise SBP [6], or SBP in 1 min of recovery [4]. However, the third-minute SBP relative to 1 min post-exercise SBP (SBPR2) is often preferred to the third-minute SBP ratio relative to peak-exercise SBP (SBPR1) because it has the advantage of the accuracy of blood pressure measurement [4], since both SBPs can be obtained only in the recovery state. This avoids the inaccuracy associated with exercise blood pressure measurement [7]. A value of the third-minute SBP ratio relative to 1 min post-exercise SBP greater than 1.0 is considered a delayed SBP recovery [4].

Since delayed SBPR is a risk factor for cardiovascular diseases, there is a need to evaluate the relationships between SBPR and factors previously associated with cardiovascular events in order to provide better basis for defining and interpreting changes in post-exercise SBP responses to physical stress in future investigations. Age, obesity index, resting heart rate (HR), physical fitness, and cigarette smoking have been associated with SBP...
response during exercise [8], and reported to be risk factors for hypertension, coronary artery disease and other cardiovascular events [8,9]. In contrast, post-exercise SBPR has been shown to indicate age and gender differences and related to physical fitness and HR during recovery [3,10,11]. However, no study to our knowledge has associated SBPR with obesity indices (body mass index (BMI) and waist circumference), resting HR or cigarette smoking. Similarly, no study has compared the predictive strength of the above variables on SBPR.

In the present study, we demonstrated whether age, sex, BMI, waist circumference, resting HR, physical activity, and cigarette smoking are independently related to post exercise SBPR or not, in Malaysian adults who performed Treadmill exercise. In addition, we determined which of these variables best predicts changes in SBPR.

2. METHODOLOGY

One hundred and fifty seven apparently healthy, normotensive subjects of both the genders (62 were males and 95 were females), apparently healthy, normotensive subjects between the ages of 18 to 66 years had selected from students and staff of Masterskill college of Nursing and Health sciences, Sabah, Malaysia. Subjects were randomly selected based on the results of a structured health and lifestyle screening questionnaire, physical examination, morphometric measurements and medical history. Information on cigarette smoking was obtained by verbal report from the subjects. Subjects were classified as smokers or nonsmokers. Physical activity status of the subjects were evaluated using the international physical activity questionnaire (IPAQ) for adults [3]. The IPAQ comprises a set of 4 questionnaires which are used to assess the physical behaviors of participants at different times and places and the time spent being physically active in the last 7 days. The reliability and validity of IPAQ has been tested and results suggest that it is an acceptable measure of physical activity in adults [3]. Based on the IPAQ scores, subjects were classified as inactive, moderately active and highly active. These scores were recorded as categorical data (inactive = 1; moderately active = 2; highly active = 3).

2.1. Inclusion Criteria

1) Ability of a subject to perform a vigorous cycle ergometer exercise at 80% of age–predicted maximum HR intensity.

2) No prior history of unstable cardiovascular, peripheral vascular and respiratory disease, malignancy, and orthopedic or musculoskeletal disorders.

3) Subjects should be non obese and non diabetics.

4) Subjects should have normal blood pressure (BP) and HR.

5) Not taking medications that could affect cardiovascular functions

6) Not menstruating at the time of test if female.

Subjects were informed (written and oral) of the experimental procedures and their consents were obtained before participation.

2.2. PROCEDURE

2.2.1 Exercise Test

The exercise tests were carried out in a well-ventilated room, using a mechanically braked cycle ergometer. With the ergometer cycling protocol, it is easy to obtain reliable blood pressure measurements especially during recovery period. The cycle ergometer usually consists of progressive incremental workloads that may have minor effects on SBPR’s achieved during the exercise test [12]. Participants were instructed not to consume beverages containing alcohol or coffee, not to eat a heavy meal, or participate in any vigorous physical activity 24 hours before the test. They were also properly instructed on how to perform the exercise test with demonstrations. The exercise protocol comprised an initial two-minute warm up at a work load of 20 Watts, followed by a linear increase of 20 Watts every minute until the subject reached the targeted percentage (80%) of age-predicted maximum HR (HR max), after which the exercise test was terminated. The HR max was determined as HR max = 208 minus (0.7 × age), [13]. The rating of perceived exertion (RPE) to exercise was obtained using the Borg’s scale [2] immediately after the exercise protocol.

2.2.2. Anthropometric Measurements

Subject’s height was measured to the nearest 0.1 cm with the use of stadiometer with the shoulders in a relaxed position and the arms hanging freely. Weight was measured to the nearest 0.1 kg in light clothing without shoes using a balance scale. BMI was calculated as weight (kg) divided by the square of the height (m²). Waist circumference was measured twice to the nearest 0.1 cm using an inelastic and flexible tape, on a horizontal plane at the end of normal expiration with subjects lightly clothed and standing. The mean of the two measurements was used for subsequent analysis. Waist circumference was measured half way between the top of the iliac crest and the lower rib margin.

2.2.3. Blood Pressure and Heart Rate Measurements

Resting BP and HR were measured after 10 and 15 minutes of rest, in a seated position and in a quiet room, one week prior to the exercise test, using the mercury-column sphygmomanometer and an automated upper arm-cuff
HR monitor (Omron Health Care Inc., Vernon Hills, Illinois) respectively. The resting BP and HR measurements were used to ascertain whether a subject had normal BP and HR or not. Immediately before the exercise test, subject’s pre-exercise BP and HR were also measured twice (after 10 and 15 minutes of rest) when sitting on the cycle ergometer. During the exercise, BP was measured at two-minute intervals and during the last minute of exercise, as soon as the subject reached his or her targeted HR. Heart rate on the other hand, was measured continuously every minute until the subject attained the targeted HR equivalent to the 80% HR max intensity. The peak-exercise BP and HR were defined as the highest values achieved at the termination of the exercise. Further BP measurements were done immediately after exercise (within the first minute of recovery) and subsequently at two-minute intervals until recovery to pre exercise level (i.e. measurements were done at 1, 3, 5, 7,…min). During the post-exercise BP measurement, subjects were asked to be in sitting position on the bicycle without pedaling while the research personnel were blinded to the test results at baseline and during exercise. First and third minutes of recovery were used to express the periods of recovery after exercise in this study, since they were available for all subjects. We evaluated SBPR using the ratio of third minute SBP relative to SBP at 1 min of recovery [14], calculated as 3 min post exercise SBP divided by 1 min post-exercise SBP. We preferred SBPR2 as our index of SBPR because both SBPs are obtained only in the recovery state, thus avoiding the inaccuracy associated with exercise blood pressure measurement [15].

2.2.4. Statistical Analyses

Descriptive data are presented as means ± SD. Data analyses between the gender groups were performed using the independent sample t-test. Pearson’s bivariate correlation test was used to evaluate the relationships between SBPR2 and age, BMI, WC, resting HR, physical activity status, and cigarette smoking in both genders. In both gender groups, all variables indicated significant and positive relationships with SBPR2 except physical activity status, which was negatively associated with SBPR2.

Table 2 shows the exercise test characteristics of subjects. Men indicated significantly higher peak-exercise SBP, peak-exercise DBP, SBPR1, and SBPR2 than did the women. Peak exercise HR and rating of perceived exertion indicated no significant differences between the genders. Changes of SBP as it falls from peak exercise to baseline during recovery are as shown in Figure 1. At 1 minute of recovery, SBP declined to 104 mmHg for males, and 173 mmHg for females, while at 5 minutes of recovery, the data indicated 140 mmHg and 141 mmHg for males and females respectively.

Table 3 shows a bivariate correlation analysis between SBPR2 and age, BMI, waist circumference, resting HR, physical activity status, and cigarette smoking in males and females. In both gender groups, all variables indicated significant and positive relationships with SBPR2 except physical activity status, which was negatively associated with SBPR2.

Table 4 reveals a multiple regression analysis to evaluate the independent relationship between SBPR2 and age, BMI, waist circumference, resting HR, physical activity status, and cigarette smoking in males and females. In men, all the variables except waist circumference remained significantly predictive of SBPR2 after adjusting for each other. In women, SBPR2 associated significantly with all the variables except BMI. Combining the data for men and women, we evaluated the independent association between gender and SBPR. A multiple regression analysis indicated a significant and independent relationship between gender and SBPR2 (r = 0.248; p < 0.001).

4. DISCUSSION

Our findings indicated that, in both genders, age, resting HR, and cigarette smoking were independently and positively associated with SBPR, while physical activity indicated negative association with SBPR; body mass index, and waist circumference were predictive of SBPR in at least one gender-specific group. Age in males and physical activity in females were the best predictors of SBPR. Changes in SBPR are thought to be due to changes in systemic vascular resistance [16,17], sympathetic and parasympathetic activities [12,16], and baroreflex sensitivity [18]. Similarly, SBPR has been reported to indicate age and gender differences and related to physical fitness and HR recovery [9,10,12]. Blunted or delayed recovery of SBP after exercise is also associated with increased risk of cardiovascular diseases [12,14,16, 19,20]. In the present study, age was inde-

and positively related to SBPR in males and females. Age has been previously associated with blood pressure responses [15]. Age differences have also been found in SBPR after exercise with the older subjects indicating
slower SBP recovery than younger adults [10]. Changes observed in blood pressure responses due to advancing age are suggested to be due to increase in systemic vascular resistance [21,22], decrease in parasympathetic activity [8], elevated sympathetic activity [23], decline in physical fitness [24], and reduced baroreflex sensitivity [25] in older adults. Ageing is also related to increased risk of cardiovascular diseases [21,22]. These factors as already stated above are associated with SBPR after exercise and may help explain the independent relationship observed between age and SBPR in the present study. Overweight and obesity have been previously related to blood pressure response during exercise [4] but not to post exercise SBPR. Previous studies [26,27] have consistently shown that both absolute total fat and adipose tissue distribution are closely associated with the risk of diabetes, hypertension, hyperlipidemia and cardiovascular diseases. BMI appears to be the best and most cited index for obesity because it approximates adiposity and fat distribution in adults [28]. It is also considered a strong predictor of metabolic risks [29]. Recent studies have also suggested that waist circumference is the best index of abdominal visceral adipose tissue [30] and may also be the best index for predicting cardiovascular risks [31].

The present data demonstrated independent and positive relationships between SBPR and BMI in males, and waist circumference in females. These findings show that an increase in level of adiposity will lead to increase in SBPR2 (slower SBPR) and also suggest that BMI was the better obesity index that explained variations in SBPR in males while waist circumference best predicted SBPR in females. Our findings concur with previous studies which have shown that central obesity is more closely associated with cardiovascular risks than general obesity in women [32,33], while general obesity best predicts cardiovascular risks in men [32]. The present data indicated that the SBP recovery ratios consistently related positively to resting HR in both genders. This indicates that a low resting HR will result in faster SBPR and vice versa. No previous study to our knowledge has associated resting HR to SBPR. The present result however was expected since changes in blood pressure are usually mediated by the baroreflex mechanism via HR changes [34]. The baroreflex mediated response of HR to changes in arterial blood pressure indicates the capacity of reflex cardiac autonomic modulation [35]. Furthermore, low resting HR has been reported to be a partial surrogate for good conditioning and regular exercise [6] and reflects good health [1], whereas higher values are related to higher cardiovascular mortality [36]. Similarly, faster SBPR after exercise has been previously related to higher physical activity and fitness level [12], while a delayed (slower) SBPR is associated with increased risk of cardiovascular diseases. The level of physical activity has been previously associated with SBP responses to exercise [37] and generally regarded as a very important risk factor for cardiovascular diseases. The rate at which SBP declines after exercise is suggested to be a reflection of a person’s level of physical activity and fitness; a more rapid decline indicates a higher level of physical fitness, and a greater decrease in SBP from peak exercise to the recovery may reflect good aerobic capacity [12]. In the present study, a higher physical activity level of subjects was associated with faster SBPR and consistent with the previous studies. The mechanisms behind the observed relationship between physical activity and SBPR are not very clear. However, this may be connected with the effect of exercise training in improving vascular endothelial functions and vasodilatory capabilities, hence a decrease in systemic vascular resistance [38,39]. Cigarette smoking has been shown to increase blood pressure and HR, decrease exercise tolerance and is associated with cardiovascular diseases such as coronary heart disease, stroke, and peripheral vascular diseases [40]. However no study has associated cigarette smoking with SBPR. In this study, cigarette smoking indicated independent and positive associations with delayed SBP recovery in both genders. Smokers showed 0.10 higher SBPR2 than non-smokers in both genders.

These results may be a reflection of poor response of SBP to exercise in poorly conditioned smokers. The mechanism by which smoking slows down SBP recovery is not well understood, but it is thought that smoking through the activities of nicotine and carbon monoxide contributes to the aggravation and acceleration of arterial wall stiffness and inelasticity [18], thus increasing systemic arterial resistance.

In order to determine the relationship between gender and SBPR, we combined the data for men and women to perform a multiple regression analysis adjusting for all
the other variables. Our data showed that men showed 0.25 higher SBPR2 than women. This result indicates that women demonstrated faster SBPR than men and inconsistent with our previous study [9]. Previous studies [12,16] have suggested that SBPR recovery will be delayed with increased sympathetic activity and attenuated vagal reactivation. It has also been reported that at all ages women have been found to have reduced sympathetic activity and enhanced parasympathetic activity relative to men [41]. Epidemiological studies have also demonstrated a gender difference in the incidence of cardiovascular disease, with women, particularly younger women, at much lower risk of developing cardiovascular disease than their age matched men [5]. These facts support our present findings in which women indicated faster SBPR than males. It is noteworthy that among all the variables studied, age in men and physical activity in women indicated the strongest associations with SBPR. Previous studies [11,12] have demonstrated the importance and influence of age and physical activity on SBPR but none to our knowledge has compared the strength of associations of predictive variables with SBP recovery. The present findings therefore may suggest that age in men and physical activity status in females should be given more importance when evaluating changes in SBP recovery and during screening of associated cardiovascular events. Further studies are however needed to strengthen these findings.

5. LIMITATIONS OF STUDY

Our study involved adults who performed ergometer exercise tests at a sub maximal level (vigorous exercise intensity). In addition, we evaluated systolic blood pressure recovery during inactive exercise recovery mode. Our study therefore may not apply to SBPR recovery from other exercise types and intensities; or to other cycling exercise recovery modes. Further studies are therefore recommended in these areas.

6. CONCLUSIONS

In summary, the present study indicated independent relationships between SBP recovery and variables known to associate with cardiovascular abnormalities such as age, BMI and waist circumference, resting HR, physical activity, and cigarette smoking in at least one gender-specific group of apparently healthy adults. These findings strengthen the previously reported prognostic importance of post-exercise SBP recovery in diagnosing cardiovascular abnormalities in healthy adults undergoing exercise stress tests. Additionally, it will provide a better basis on which to define and interpret the mechanisms behind changes in post-exercise SBP responses in healthy adults undergoing stress tests in future investigations.
