Comment:
The paper does not meet the standards of "International Journal of Medical Physics, Clinical Engineering and Radiation Oncology ".

This article has been retracted to straighten the academic record. In making this decision the Editorial Board follows COPE's Retraction Guidelines (http://publicationethics.org/files/retraction%20guidelines.pdf). The aim is to promote the circulation of scientific research by offering an ideal research publication platform with due consideration of internationally accepted standards on publication ethics. The Editorial Board would like to extend its sincere apologies for any inconvenience this retraction may have caused.
Usefulness of Iron-Containing Fiducial Marker for Prostate Radiotherapy

Abstract
Visualization of markers is critical for imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI). However, the size of the marker varies according to the imaging technique. While a large-sized marker is more useful for visualization in MRI, it results in artifacts on CT and causes substantial pain on administration. In contrast, a small-sized marker reduces the artifacts on CT but hampers MRI detection. Herein, we report a new iron-containing marker and compare its utility with that of non-iron-containing markers. Five patients underwent CT/MRI fusion-based intensity-modulated radiotherapy, and the markers were placed by urologists. A Gold Anchor™ (GA; diameter, 0.28 mm; length, 10 mm) was placed using a 22 G needle on the right side of the prostate. A VISICOIL™ (VIS; diameter, 0.35 mm; length, 10 mm) was placed using a 19 G needle on the left side. MRI was performed using T2*2-dimensional-weighted imaging. Three observers evaluated and scored the visual qualities of the acquired images. The mean score of visualization was almost identical between the GA and VIS in radiography and cone-beam CT (Novalis Tx). The artifacts in planning CT were slightly larger using the GA than using the VIS. The visualization of the marker on MRI using the GA was superior to that using the VIS. In conclusion, the visualization quality of radiography, cone-beam CT, and planning CT was roughly equal between the GA and VIS. However, on MRI, the GA was more strongly visualized than the VIS because of its iron content.

Keywords
Prostate Radiotherapy, Image-Guided, MRI, Fiducial Marker

1. Introduction
The precision of radiotherapy for prostate cancer has been improving, and intensity-
modulated radiotherapy (IMRT) is commonly performed using fiducial markers [1] [2] [3], because the treatment must often be repeated and markers capable of being depicted on magnetic resonance imaging (MRI) are necessary. Herein, we report our findings regarding the utility of a 0.5%-iron-containing fiducial marker (Gold Anchor™ [GA]; Naslund Medical AB, Huddinge, Sweden) versus a commonly used linear fiducial marker (VISICOIL™ [VIS]; RadioMed Corporation, Bartlett, TN, USA) in five patients at our hospital.

2. Materials and Methods

From April to May 2016, five patients participated in this study. All of the patients provided written informed consent. The fiducial marker was placed by urologists via the transperineal method under local anesthesia. The VIS was placed on one side of the prostate, and the GA was placed on the opposite site.

The GA was 0.28 mm in diameter and 10 mm in length and had a winding, zigzag shape that could be bent to make the marker spherically shaped (Figure 1). The VIS was 0.35 mm in diameter and 10 mm in length and was linear, as is most common. The Gas was inserted using 22 G needles, and the VISs were inserted using 19 G needles (the thinnest needle available for the VIS in Japan). Patients on anticoagulants were excluded from the study. Three weeks after the insertion of the GA and VIS, computed tomography (CT) and MRI were performed.

2.1. Image Acquisition

- $T_1$-weighted imaging ($T_1$-WI): $T_1$-weighted spin-echo. Repetition time (TR)/echo time (TE) range in milliseconds: 400-650/8; number of averages (NA): 4; number of

![Gold Anchor 0.28 mm VISICOIL 0.35 mm](image)

**Figure 1.** Marker characteristics. The Gold Anchor can be used with needles as thin as 25 G and placed spherically. It contains 0.5% iron and is highly visible on MRI. The VISICOIL is a coiled, straight, flexible linear marker requiring a 22 G needle, and it exhibits little migration.

The patients drank 200 ml of water 30 minutes before undergoing CT (Optima CT580; GE Medical Systems, Milwaukee, WI, USA) and MRI (Intera 1.5 Nova; Philips Medical Systems, Eindhoven, The Netherlands) and provided urine samples. MRI was performed within 20 minutes after CT. All of the patients were given butylscopolamine to stop bowel movements.

MRI was performed with 3-mm section thickness, no intersection gaps, and a 16-cm field of view using a cardiac coil. The sequence was as follows: T1-WI, T2-WI, T2*2D-WI, T2*3D-WI, and contrast-enhanced T1-WI. The details of the modalities are described above.

We evaluated the images obtained using T2-WI, T2*2D-WI, and T2*3D-WI among the five sequences because these showed the best visualization. We primarily examined the degree of artifacts on CT and marker visualization on MRI.

The radiotherapy instrument used was a Novalis Tx system (Varian Medical Systems, Inc., Palo Alto, CA, USA). Before we began the present study, the 0.35 mm × 10 mm and 0.5 mm × 10 mm VIS markers had been well recognized visually on cone-beam CT in all cases.

### 2.2. Evaluation of Images

The degree of recognition of the prostatic outline despite artifacts on CT was scored as follows: 1, poor; 2, slightly poor; 3, neutral; 4, marginally good; and 5, excellent. The degree of recognition of the marker itself on the prostate on MRI was scored as follows: 1, poor; 2, slightly poor; 3, neutral; 4, marginally good; and 5, excellent. The degree of recognition of the marker and the prostatic outline on MRI was analyzed, and we adopted the best sequences among T2-WI, T2*2D-WI, and T2*3D-WI. Urologists also evaluated the visibility of the marker and needle on transrectal echography. The Institutional Review Board approved this study (No. 265), and the trial was registered on the UMIN Clinical Trials Registry (Clinical Trial Registration No. 22635).

### 2.3. Results

We did not conduct any statistical analyses in this study of five patients. We en-coun-
tered no difficulties during pelvis plain radiography using either the GA or VIS (Figure 2). On CT, the GA produced moderately bigger artifacts than did the VIS, but the GA did not influence the visualization of the prostate or surrounding organs (Figure 3). However, the visibility on MRI was clearly better when using the GA than when using the VIS (Figure 4). The GA had a visibility similar to that of coarse calcification (Figure 5). In contrast, the VIS (0.35 mm) was slightly difficult to visualize on MRI. Nevertheless, both markers could be recognized equally well on transrectal echography.

3. Discussion

The clinical results of radiotherapy depend on the reproducibility of high-precision techniques such as IMRT throughout the radiotherapy course, because we monitor the dynamics and increase the dosage to the prostate or reduce the dosage to the surrounding normal tissues based on these findings. In addition, real-time tracking can reduce
the risk of complications associated with IMRT at the location of the prostate, which varies within the body.

However, the prostatic outlines are indistinct, and treatment adjustment and contouring of the organs can prove difficult when using CT alone. As such, MRI is often used to compensate for any shortcomings of CT [4] [5]. Because the prostatic outlines are clearer on MRI, it is performed after CT and is registered under the guidance of markers.

Marker sizes vary globally and range in diameter from 0.35 mm to 1.1 mm and in
length from 10 mm to 30 mm. At present, a diameter of 0.75 mm and length of 0.5 mm are most frequently used in Japan. The recognition precision on MRI increases with marker size, thereby simplifying the treatment. However, the recognition precision on CT decreases with increasing marker size, as artifacts begin to appear when a large volume of metal is present. In addition, the prostate is a small organ, and the presence of metal either in the marker or within the organ itself may influence the dose distribution. Tanaka et al. developed an optimal MRI sequence based on marker size, and a marker diameter of 0.35 mm has since been adopted at our hospital [4] [5].

In February 2016, however, a marker with a diameter of 0.28 mm, a 22 G needle, and iron-containing markers became available in Japan. The GA used in the present study contains 0.5% iron, and its visibility on MRI is reported to be superior to that of non-iron-containing markers. Iron-containing markers have been widely used in other countries since 2010, and previous studies have reported fewer artifacts on CT and increased visibility on MRI when using these markers than when using the conventional gold markers.

Most facilities use 0.35- to 0.75-mm-diameter markers, but recently, by virtue of repeated experience, the 0.5-mm-diameter marker has been preferred. We employed a 0.35-mm marker because it was well recognized on cone-beam CT and helped reduce the artifacts on CT. To our knowledge, no previous studies have compared the outcomes of the GA with those of other markers in the same individual, albeit we did find some reports of phantom studies [5].

At present only 19 G needles can be sold in Japan, and 22 G needles for VIS are still not available. Nevertheless, in this initial experience of five cases, the chalybeate marker greatly contributed to registration using MRI for radiation treatment planning in clinical practice.

4. Conclusion

Our findings show that an iron-containing marker is extremely useful in image registration. Bleeding and pain can be avoided by using a thin needle, and the marker can be recognized on prostatic MRI even when using a thin 22 G needle. The present findings suggest that the Gold Anchor will indeed be useful in daily practice.
